younger patients had a worse prognosis (Fig. 1). The discriminant analysis for the prediction of sudden death included clinical features of severe functional impairment as well as young age and unfavorable family history. However, in the young patients, sudden death was clearly unrelated to severe functional limitation, elevated filling pressure or the presence of a left ventricular outflow tract gradient (Tables VI to VIII). One may speculate that the mechanism of death may be accelerated by worsening hemodynamic state in the older patients but that the underlying mechanism is unlikely to be hemodynamic in the majority of patients; 12 (32 percent) of the 38 dead patients were aged 30 years or younger and 69 percent were in functional class I. Syncope was the only clinical feature associated with sudden death, particularly in patients younger than 45 years ($p < 0.01$) (Table VI).

Mechanisms of sudden death: It is unreasonable to assume that the mechanism of sudden death is the same in all patients with hypertrophic cardiomyopathy; isolated reports of cardiac asystole,[5] massive myocardial infarction[24] and rapid atrioventricular conduction through an accessory pathway degenerating to ventricular fibrillation[16] have been documented as antecedent events. Primary hemodynamic mechanisms, with increased left ventricular outflow tract gradient or tachycardia with acute decrease in stroke volume, have also been proposed.[25] Although it remains unproved, we suspect that ventricular arrhythmia is the antecedent event in most sudden deaths in patients with hypertrophic cardiomyopathy. The large incidence of serious ventricular arrhythmia is well recognized,[26–28] and in our series 55 percent of the deaths were sudden and were associated with a previous history of syncope. Traditional treatment with beta adrenergic blocking drugs[27,28] and the newer treatment with verapamil[29] are ineffective against ventricular arrhythmias in hypertrophic cardiomyopathy. The high (50 percent) incidence rate[26,27] of serious ventricular arrhythmia in

hypertrophic cardiomyopathy was not recognized before the development of ambulatory electrocardiographic monitoring, and only 7 percent of the 254 patients received specific antiarrhythmic drugs other than beta blocking agents or verapamil. Because the detection and effective treatment of arrhythmia may improve prognosis in this condition, we are investigating the value of amiodarone and similar antiarrhythmic agents.

Comparison of Coronary Arteriographic Findings During Angina Pectoris Associated With S-T Elevation or Depression

HIROFUMI YASUE, MD

Coronary arteriographic findings during an attack of angina pectoris associated with S-T segment elevation and angina associated with S-T depression were compared in 54 patients. Thirty-eight attacks with S-T segment elevation included 2 that were spontaneous, 6 induced by methacholine, 4 by epinephrine with or without propranolol, 9 by arm exercise, 5 by hyperventilation with or without Tris-buffer infusion and 12 by ergonovine maleate. Twenty-nine of the 38 attacks were associated with total occlusion, 8 with subtotal occlusion and 1 with diffuse narrowing of a major coronary artery caused by spasm.

Twenty-six attacks with S-T segment depression included 3 induced by methacholine, 13 by arm exercise, 3 by hyperventilation with or without Tris-buffer infusion and 7 by ergonovine maleate. Eight of the 26 attacks were associated with subtotal occlusion and 9 with diffuse narrowing of a major coronary artery caused by spasm; 3 attacks were associated with total occlusion of a major coronary artery well supplied with collateral vessels and 2 with total occlusion of a small coronary branch caused by spasm. Four attacks were associated not with spasm but with fixed subtotal occlusion of a major coronary artery (3 attacks) or total occlusion of a major coronary artery receiving collateral vessels (1 attack).

Only 2 of the 31 patients with S-T segment elevation had collateral vessels compared with 8 of the 16 patients with S-T segment depression ($p < 0.001$). It is concluded that angina pectoris associated with S-T segment elevation usually indicates more severe myocardial ischemia than angina associated with S-T segment depression.

S-T segment displacement in the electrocardiogram is one of the most useful signs of acute myocardial ischemia, but the difference between angina pectoris associated with S-T segment elevation and that associated with S-T depression has not been fully elucidated.[1–5] Experimental studies[2,6–8] suggest that S-T segment elevation is associated with more severe ischemia than is S-T depression, the former representing transmural ischemia and the latter subendocardial ischemia.[9–11] We have reported coronary arteriographic findings during angina associated with S-T elevation and during angina associated with S-T depression. In this study, we reviewed and compared the coronary arteriographic findings during angina associated with S-T segment elevation and depression.

Methods

Study patients: We were able to perform coronary arteriography during 64 attacks of angina pectoris (38 associated with S-T segment elevation and 26 with S-T segment depression) in 54 patients. The patients' age and sex, the electrocardiographic findings during angina, coronary arteriographic findings after nitroglycerin administration and in the absence of angina and during angina are shown in Table I. Thirty-one patients (Cases 1 to 31) had recurrent angina associated with S-T segment elevation occurring spontaneously and 17 of the 31 also had exertional angina on occasion. Seven patients (Cases 32 to 38) had spontaneous angina associated with either S-T segment elevation or S-T segment depression in the same leads and four of the seven also had exertional angina

on occasion. Sixteen patients (Cases 39 to 54) had exertional angina associated with S-T segment depression and eight of them also had spontaneous angina. Patients with myocardial infarction or heart failure were excluded from the study.

Electrocardiography: Standard 12 lead electrocardiograms were taken repeatedly during angina and transient S-T segment elevation of more than 2.0 mm or transient S-T segment depression of more than 1.0 mm from baseline was documented in all patients. S-T segment elevation with reciprocal S-T segment depression in opposing leads was classified as S-T segment elevation.

Methods of provoking angina: Details of the methods of provoking angina have previously been reported.[9–13] These methods have been confirmed to be safe in experienced hands

S1 to S15 refer to the segment of the coronary arteries as defined by the American Heart Association Report[14]; S-T ↑ and ST ↓ = S-T segment elevation and depression, respectively.

at our institution. Multiple provocative methods were used because in any one patient one test could be provocative and another not. For example, when arm exercise failed to provoke an attack, ergonovine was successful. Most of the attacks during coronary arteriography were induced in the early morning (from 5:00 a.m. to 8:00 a.m.). Of the 38 attacks associated with S-T segment elevation during coronary arteriography, 2 were spontaneous, 6 were induced by subcutaneous injection of methacholine (10 mg), 4 by subcutaneous injection of epinephrine (0.4 to 0.5 mg) with or without prior oral administration of propranolol (40 to 60 mg), 9 by arm exercise, 5 by hyperventilation with or without Tris-buffer infusion and 12 by intravenous injection of ergonovine maleate (0.05 to 0.2 mg).

Of the 26 attacks associated with S-T segment depression during coronary arteriography, 3 were induced by subcutaneous injection of methacholine (10 mg), 13 by arm exercise, 3 by hyperventilation with or without Tris-buffer infusion and 7 by intravenous injection of ergonovine maleate (0.05 to 0.2 mg).

Coronary arteriography: Coronary arteriography was performed in the morning with the Judkins technique with constant monitoring of the electrocardiogram and blood pressure. Administration of all medications except nitroglycerin had been stopped at least 2 days before the procedure, and use of nitroglycerin had also been stopped at least 2 hours before the procedure. Coronary arteriography was done before, during and after an attack of angina. The angina was relieved promptly by sublingual administration of nitroglycerin, 0.6 mg.

Written informed consent was obtained from each patient.

Results

Coronary arterial spasm: Coronary arteriography demonstrated that spasm of an artery supplying the area of myocardium represented by S-T segment shift in the electrocardiogram appeared during an attack of angina and disappeared with subsidence of the attack after nitroglycerin administration in all 38 attacks associated with S-T segment elevation and in 22 of the 26 attacks associated with S-T depression (Table I). Four attacks with S-T depression (Cases 47 to 50) were not associated with an appreciable coronary arterial spasm.

Degree and location of spasm (Fig. 1): Coronary arteries in the arteriograms were divided into 15 segments according to the classification of the American Heart Association Committee Report.[14] Of the 38 attacks with S-T elevation, 29 were associated with total occlusion, 8 with subtotal occlusion (99 percent of luminal diameter) and 1 with spasm-induced diffuse narrowing (60 to 90 percent of luminal diameter) of a major coronary artery. Total occlusion was generally associated with more severe S-T elevation than was subtotal occlusion or diffuse narrowing.

Thus, the majority (76.3 percent) of the attacks with S-T elevation were associated with total occlusion of a major coronary artery.

Of the 26 attacks of angina associated with S-T depression, 8 were associated with subtotal occlusion and 9 were associated with diffuse narrowing of a major

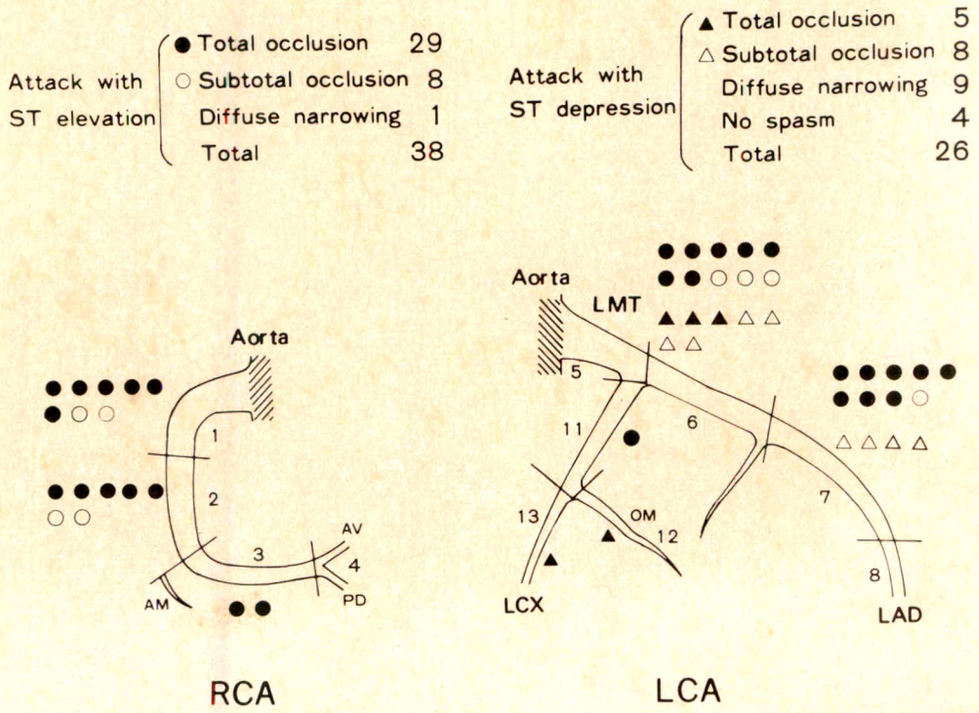

FIGURE 1. Coronary arteriographic findings during acute angina with S-T segment elevation and acute angina with S-T depression. Coronary arteries were divided into 15 segments according to the American Heart Association Committee Report[14] as shown by the number in the diagram of coronary arteries. AM = acute marginal branch; AV = A-V nodal branch; LAD = left anterior descending coronary artery; LCA = left coronary artery; LCX = left circumflex coronary artery; LMT = left main trunk; OM = obtuse marginal branch; PD = posterior descending branch; RCA = right coronary artery.

coronary artery caused by spasm. In two patients (Cases 40 and 52) spasm totally occluded the left anterior descending artery at segment 6 during the attack, but there was a rich supply of collateral vessels to the distal part of this segment in both patients. In one patient (Case 45) spasm totally occluded the poorly developed left circumflex artery at segment 13 during the attack, and in one patient (Case 39) spasm totally occluded the left circumflex artery at segment 12 (obtuse marginal branch). In four patients (Cases 47 to 50), the attacks were associated not with spasm, but with fixed subtotal occlusion of a major coronary artery (Cases 48 to 50) or total occlusion of a major coronary artery receiving collateral vessels (Case 47).

In two patients (Cases 32 and 33) whose attacks were associated with either S-T elevation or S-T depression in the same leads, coronary arteriograms were obtained during both types of attack. In both patients angina with S-T elevation was associated with total spastic occlusion of a major coronary artery (Fig. 2 and 3), whereas angina with S-T depression was associated with either subtotal occlusion (Case 32, Fig. 2) or diffuse narrowing (Case 33, Fig. 3) of the same artery.

Thus, the majority (76.9 percent) of anginal attacks associated with S-T segment depression were accompanied by either subtotal spastic occlusion or diffuse narrowing of a major coronary artery. When the attack with S-T segment depression was associated with total occlusion, the occlusion occurred either in a major coronary artery receiving many collateral vessels to its periphery or in a small branch of a major coronary artery.

Extent of coronary artery disease: Coronary artery disease was defined as fixed arteriographic narrowing greater than 50 percent of luminal diameter. Of the 31 patients with angina associated with S-T segment elevation, 9 had normal coronary arteries and 16 had single, 3 double and 3 triple vessel disease. Of the seven patients with angina associated with either S-T segment elevation or depression in the same leads, 2 had normal coronary arteries and 5 had one vessel disease. Of the 16 patients with angina associated with S-T segment depression, 2 had normal coronary arteries and 9 had single, 4 double and 1 triple vessel disease.

Thus, there was no difference in the extent of coronary artery disease in patients whose angina was asso-

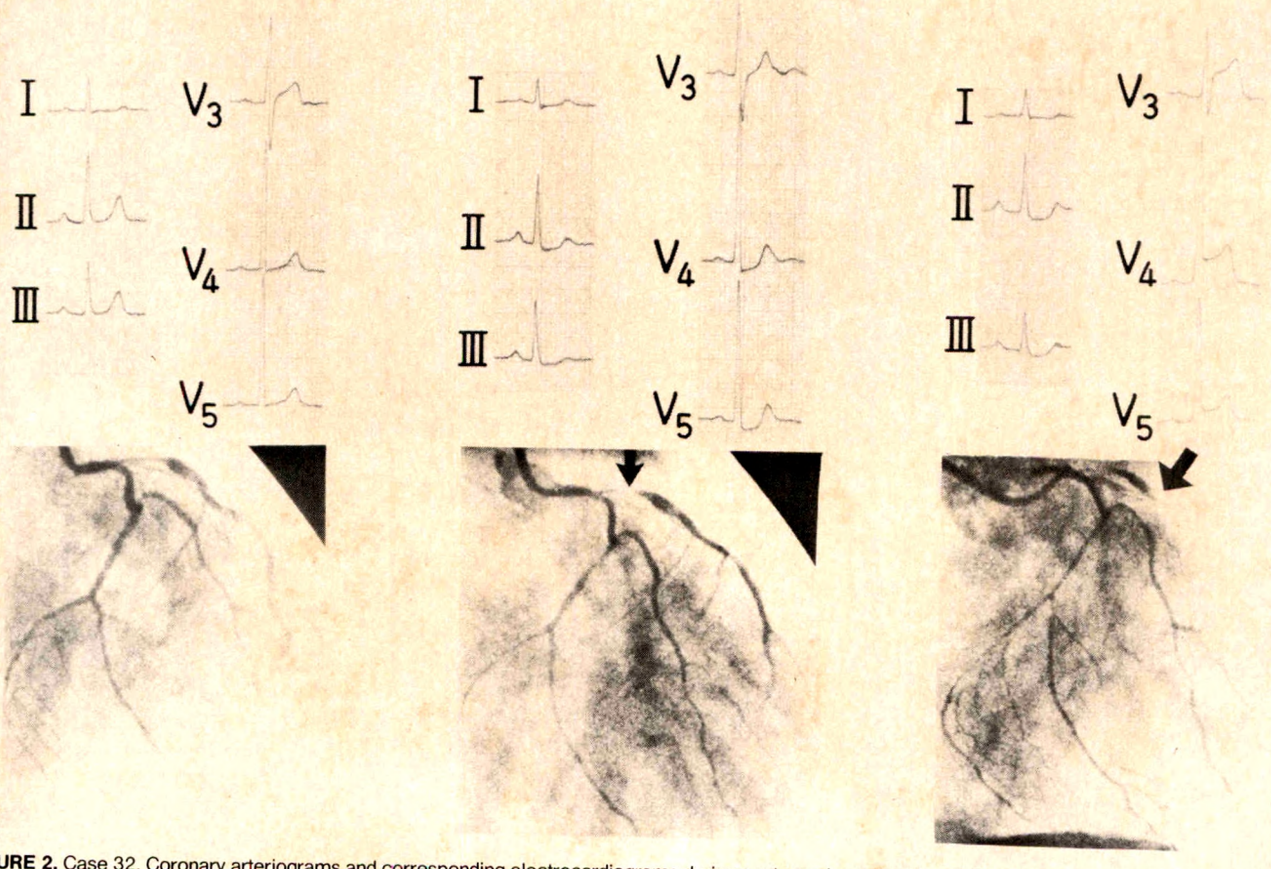

FIGURE 2. Case 32. Coronary arteriograms and corresponding electrocardiograms during acute angina with either S-T segment elevation or depression in the precordial leads. During angina with S-T elevation, spasm totally occluded the left anterior descending coronary artery at segment 6 (**right**). During angina with S-T depression, spasm subtotally occluded the same artery at the same segment (**center**). The **left panel** shows the control coronary arteriogram and electrocardiogram.

ciated with S-T segment elevation or depression. But this finding was probably related to the small number of patients with multivessel disease included in this study.

Collateral circulation: Collateral circulation was present in 2 of the 31 patients with S-T segment elevation and in 8 of the 16 patients with S-T segment depression. This difference was statistically significant ($p < 0.001$). None of the seven patients with either S-T elevation or S-T depression in the same leads had collateral circulation.

Discussion

Angina pectoris is usually associated with either S-T segment elevation or S-T segment depression in the electrocardiogram. Experimental animal studies[2,6–8] suggest that S-T elevation is associated with more severe (transmural) ischemia and S-T depression is associated with less severe (subendocardial) ischemia. Ekmekci et al.[2] demonstrated in the dog that total ligation of a major coronary artery produced S-T elevation in the ischemic area and that S-T depression replaced S-T elevation when the ligation was released or collateral circulation was supplied to the ischemic area. Kato et al.[7] also showed in the dog that S-T elevation was associated with more severe constriction of a major coronary artery than was S-T depression and that total occlusion of a small branch produced S-T depression.

Degree of coronary constriction and myocardial ischemia in angina with S-T elevation versus S-T depression: The results of our study in human beings are in agreement with the data from these animal experiments. Almost all of the acute attacks of angina pectoris with S-T segment elevation were associated with total or subtotal occlusion of a major coronary artery caused by spasm and the degree of S-T elevation paralleled roughly the degree of constriction of the artery. In contrast, angina pectoris with S-T depression during the attack was associated with either less severe spastic constriction (diffuse narrowing or subtotal occlusion) of a major coronary artery or total occlusion of a major coronary artery receiving a rich supply of collateral vessels or total occlusion of a small coronary branch. Moreover, 8 of the 16 patients with S-T depression had collateral vessels compared with only 2 of the 31 patients with S-T elevation.

Thus, it is reasonable to conclude that angina pectoris with S-T segment elevation is usually associated with more severe myocardial ischemia than is angina pectoris with S-T depression, the former representing transmural ischemia and the latter subendocardial ischemia as demonstrated in animal experiments.

Role of coronary spasm: All 38 anginal attacks with S-T segment elevation and 22 of the 26 attacks with S-T depression in our study were associated with coronary arterial spasm. Thus, coronary spasm plays an important role in the production of angina associated with S-T segment elevation as well as, in some cases, that associated with S-T depression. These observations are in agreement with those of Maseri et al.[15,16] Our study also

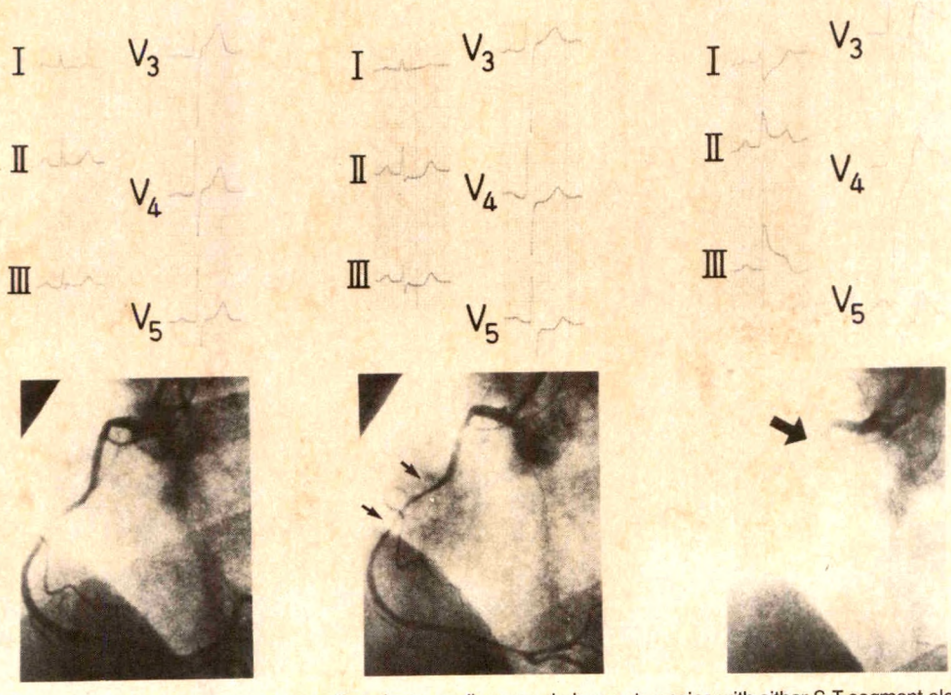

FIGURE 3. Case 33. Coronary arteriograms and corresponding electrocardiograms during acute angina with either S-T segment elevation or depression in the inferior leads. During angina with S-T elevation, spasm totally occluded the right coronary artery at segment 1 (**right**). During angina with S-T depression, diffuse narrowing of the same artery appeared (**center**). The **left panel** shows the control arteriogram and electrocardiogram.

confirms our previous findings[10,11] that coronary arterial spasm can be a cause of some exertional angina.

Implications: Our results do not necessarily support that angina pectoris is almost always caused by coronary arterial spasm. There may be many patients whose anginal episodes are not associated with appreciable spasm. Our observations were limited to a small number of patients whose anginal attacks could be induced in the catheterization laboratory by the methods described, usually in the early morning.

Coronary Flow Studies in Patients With Left Ventricular Hypertrophy of the Hypertensive Type

Evidence for an Impaired Coronary Vascular Reserve

Increased myocardial blood flow occurs in ventricular hypertrophy, but flow per 100 grams of myocardium remains normal. The increase in flow may be obtained at the expense of the existing coronary vascular reserve or by an increase in the vascular bed. The coronary vascular reserve was studied by analyzing the hyperemic reaction to selective injection of contrast agent into the coronary arteries in 25 patients: a control group (9 patients) with chest pain syndrome, normal coronary arteries and a normal left ventricle (Group I) and 16 patients with aortic stenosis, left ventricular hypertrophy and normal coronary arteries (Group II). The hyperemic response in Groups I and II was 73.3 ± 2.2 and 65.8 ± 9.1 percent, respectively (difference not significant). Group II was subdivided into two groups: Group IIA had five patients with a left ventricular mass of less than 200 g (mean 158.8 ± 25.9); this group had a hyperemic response of 102.3 ± 9.9 percent. Group IIB had 11 patients with a left ventricular mass of more than 200 g (mean 308.9 ± 22.5) and a hyperemic response of 49.27 ± 10.42 percent. The hyperemic response was correlated with the diastolic left ventricular-aortic gradient ($r = +0.64$, $p < 0.001$), left ventricular mass ($r = -0.51$, $p < 0.01$) and aortic diastolic pressure ($r = +0.636$, $p < 0.001$). Group I had a left ventricular mass similar to that of Group IIA (124.9 ± 9 and 158.8 ± 26 g, respectively) but a lower hyperemic response (73.3 ± 2 and 102.3 ± 10 percent, respectively).

These data suggest that severe left ventricular hypertrophy is associated with a reduction in coronary vascular reserve; it is speculated that this decrease in the vascular reserve capacity may be related to the ischemic component of hypertrophic heart disease.

Under physiologic conditions, coronary blood flow can increase 2 to 4 times to meet the increased myocardial oxygen requirements associated with exercise or other stresses.[1] This constitutes the most important reserve mechanism, because the myocardial oxygen extraction is large (±75 percent) under resting conditions[2] and further oxygen availability is limited upon increased demands.

In chronic left ventricular hypertrophy, coronary blood flow per unit mass of myocardium has been found normal at rest.[3–6] Histopathologic studies[7–9] have demonstrated that the myocardial fiber to capillary ratio remains unchanged, with a consequent decrease in the observed capillary density. If hyperplasia of the coronary vasculature is inappropriate or nonexistent, the increase in coronary blood flow required to keep the normal flow per gram of myocardium can only be achieved by coronary vasodilation. If this occurs, the coronary vascular reserve would be limited and this effect would be more profound in the deep subendocardial layers of the myocardium.

It has been demonstrated[10] that the injection of contrast agent into the left coronary artery causes a significant increase in coronary flow.

This increase in flow, or hyperemic reaction, represents vasodilation and decreased coronary vascular resistance. In this study the coronary vascular reserve was evaluated in patients with left ventricular hypertrophy secondary to aortic stenosis, by analysis of the hyperemic reaction to injection of contrast medium into the coronary arteries.

Methods

Patient selection: Twenty-five patients undergoing diagnostic cardiac catheterization and coronary angiography for chest pain syndrome or aortic stenosis were studied. There were 14 men and 11 women, aged 33 to 74 years (mean 56). All patients had normal coronary arteries as defined by selective coronary arteriography.

The control group (Group I) had nine patients. They all had chest pain syndrome and normal findings on catheterization and echocardiography. Group II had 16 patients with aortic stenosis undergoing catheterization for preoperative evaluation or for determination of the severity of the stenosis. This group was further divided into Groups IIA and IIB according to left ventricular mass.

It is recognized that the weight of a normal left ventricle in adults is 203 g or less in men and 141 g or less in women.[11] Accordingly, Group II was divided into Group IIA (mass less than 203 g for men or 141 g for women) and Group IIB (mass greater than 203 g for men and 141 g for women).

Cardiac catheterization: All patients signed informed consent before cardiac catheterization and agreed to have coronary sinus flow measurements performed, according to a protocol approved by the Mount Sinai Medical Center Research Administrative Committee.

Patients were premedicated with 10 mg of oral diazepam and fasted for at least 10 hours before catheterization. Under local anesthesia with 1 percent lidocaine (Xylocaine®), cutdown was performed in the right antecubital fossa. Coronary sinus flow studies were always performed before diagnostic catheterization. After systemic heparinization, a Sones catheter was introduced through the right brachial artery, and pressures were measured in the aorta and the left ventricle. One selective injection of contrast medium was performed into the right and left coronary arteries. It was estimated that sufficient time elapsed between the initial coronary injections (5 cc into the left and 3 cc into the right coronary artery) and the start of coronary flow measurements, so that no residual effect on the coronary flow or the hemodynamic variables would remain.

If no coronary disease was present, a multithermistor thermodilution catheter was introduced into the coronary sinus for measurement of coronary sinus flow; the position of the coronary sinus catheter was verified under fluoroscopy by injection of 2 to 3 ml of contrast medium. Resting coronary sinus flow was then recorded. While coronary sinus flow was being obtained, a hand injection of 5 to 10 ml of 76 percent Renografin® (meglumine diatriazoate) was performed to obtain full opacification of the left coronary artery; the hyperemic response that followed was recorded. Measurement continued until the coronary sinus flow returned to baseline. In 10 patients the dose-response effect of the contrast agent was studied by repeated, alternating injections of 5 and 10 ml of 76 percent Renografin.

No deep inspiration or holding of respiration was requested from the patient during this injection to avoid the shift in baseline. A demand pacemaker connected to the coronary sinus catheter electrodes was set at five beats less than the resting heart rate to avoid the bradycardia induced by the injection of contrast medium. The patient was in the supine position. The same procedure was repeated at least three times in each patient, with an interval of 3 to 8 minutes between each dye injection.

After these initial measurements, the coronary sinus flow catheter was withdrawn and diagnostic cardiac catheterization proceeded in the usual fashion. All studies were performed before diagnostic cardiac catheterization. No complications resulted from this procedure in this group of patients.

Recordings and measurements: *Voltage in the electrocardiogram* was measured by adding the voltages of the R wave in lead I plus the S wave in lead III and the voltages of the S wave in lead V_1 or V_2 plus the R wave in lead V_5. S-T segment depression with T wave inversion in leads V_4, V_5, and V_6, the so-called "strain pattern"[12] (Fig. 1), was noted when present.

Left ventricular and aortic pressures were recorded with the Sones catheter and a P23D Statham transducer. In nine cases these pressures were also recorded with a high fidelity Millar catheter. Left ventricular and aortic systolic pressures were measured as peak systolic pressures. Left ventricular mean diastolic pressure was calculated as an average of three points in diastole: initial, mid and late diastole. Left ventricular end-diastolic pressure was measured at the top of the R wave. Aortic diastolic pressure was measured as end-diastolic pressure. Left ventricular aortic systolic gradient was calculated as the difference between peak left ventricular and peak aortic systolic pressure. Left ventricular-aortic diastolic gradient was calculated as the difference between peak left ventricular and peak aortic systolic pressures. Left ventricular-aortic diastolic gradient was calculated as the difference between mean left ventricular diastolic pressure and aortic diastolic pressure. Cardiac output was determined by thermodilution technique with a 7 French Swan-Ganz catheter. Aortic valve area was calculated using the formula of Gorlin and Gorlin.[13]

Echocardiograms were performed just before catheterization or 1 day before. Patients with less than optimal tracings were not entered into the study. The thickness of the

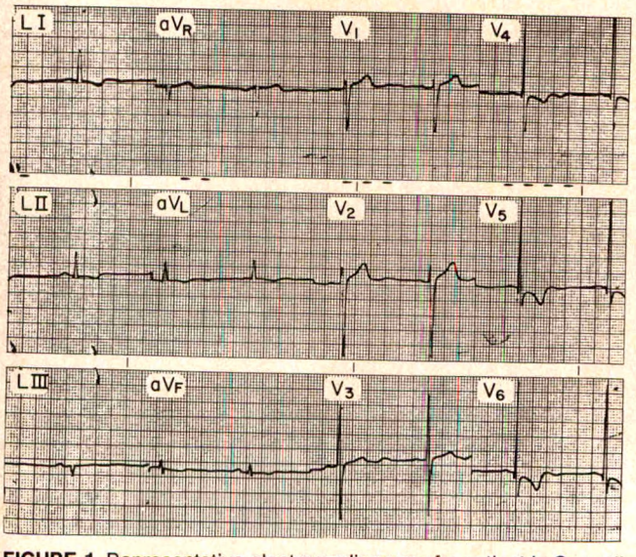

FIGURE 1. Representative electrocardiogram of a patient in Group II showing left ventricular hypertrophy and a "strain pattern."

septum (IVS_d) and the left ventricular posterior wall ($LVPW_d$) were measured in millimeters using the standard convention,[14] which includes the endocardium in the measurement; they were measured in diastole, before the *a* wave; the dimension of the left ventricular cavity was measured at this same point in diastole ($LVID_d$). Left ventricular (LV) mass was calculated using this formula[14]: LV mass (g) = $0.77 \times 10^3 [(LVID_d + LVPW_d + IVS_d)^3 - (LVID_d)^3] + 2.4$.

Coronary sinus blood flow was determined with the continuous thermodilution technique of Ganz et al.,[15] using a preshaped coronary sinus catheter with two thermistors and two pacing electrodes (Wilton Webster Laboratories). Coronary sinus flow at rest was obtained before any intervention. Hyperemic flow was defined as the maximal flow recorded after the injection of contrast medium into the left coronary artery. Percent increase in coronary sinus flow was calculated as follows: [(Hyperemic flow − Resting flow)/Resting flow] ×100. The position of the coronary sinus catheter was verified under fluoroscopy by injection of 2 to 3 ml of contrast medium and by cinearteriography during the venous phase of each injection into the left coronary artery. If the posterior interventricular vein drains very near the right atrium, its flow might not be included in the reading obtained by this technique[15]; whereas, if the thermistor is very close to the drainage site of the coronary sinus, it is more likely to have right atrial contamination, especially if right atrial pressure is elevated.[16] In addition, the position of the catheter may vary during the study or it may purposely be placed further into the coronary sinus if its position is not stable. For these reasons, the absolute values of coronary sinus flow were considered not to represent accurately total left ventricular venous outflow. Instead, the percent change in coronary sinus flow during hyperemia was analyzed.

Data from the coronary sinus flow measurements were recorded on an Electronics for Medicine recorder at a paper speed of 2.5 or 5 mm/s (Fig. 2). Data were digitized using a graph pen sonic digitizer, and analyzed by a PDP 11/70 computer. Coronary sinus flow, left ventricular mass and percent increase in coronary sinus flow were calculated by computer. Echocardiographic dimensions were measured by another investigator without knowledge of the results of the sinus flow measurements.

Validation of method: Flow measurements obtained by the thermodilution technique were validated in the following manner: a Sarns roller pump that generates a pulsatile flow was connected to a thermostatically controlled saline bath at 36.5°C and to a gradated empty glass container by a 3/8 inch (0.92 cm) Silastic® transparent tubing. Flow per minute was measured by timed collection into the gradated container. The thermodilution catheter was placed into the distal end of the Silastic tubing for flow determination. Forty-three measurements were made, with flow ranging from 70 to 810 ml/min. The correlation coefficient was +0.991 with a slope of 1.07 ± 0.02 ($b \pm S_b$).

Statistical analysis: Frequencies or means and standard errors were recorded for each measurement by groups: I, IIA and IIB. Overall comparisons among the three groups for all continuous measurements were made using analysis of variance. Pairwise comparisons (Group I versus II (A + B), Group I versus IIA, and so on) were made using Fisher's protected least significant difference technique[17] with $\alpha = 5$ percent. Pearson's product-moment correlation coefficients were calculated to determine the association of all continuous measurements with the percent change in coronary sinus flow. For the frequency-type data, Fisher's exact test[18] and the chi-square test were used. For the study comparing the hyperemic response to 5 ml versus 10 ml of the contrast agent, the paired *t* test was used.

Results

Clinical and hemodynamic data: Table I summarizes the clinical and hemodynamic data on these 25

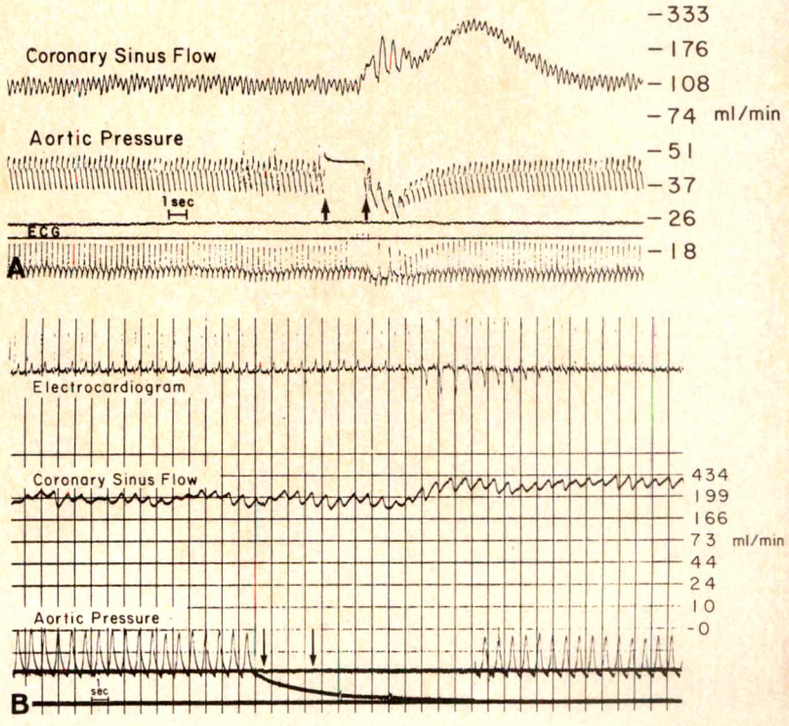

FIGURE 2. Coronary sinus flow tracings in a patient from Group I(**A**) and a patient from Group II(**B**). * $p < 0.05$ by analysis of variance for groups I, IIA and IIB. † $p > 0.05$ by analysis of variance for groups I and II.
Ao = aorta; CSF = coronary sinus flow; IVS = interventricular septum; LVID = left ventricular internal diameter; LVPW = left ventricular posterior wall; R in V_1 + S in V_3 = the sum of voltages of the R wave in lead V_1 and the S wave in lead V_3; S in V_1 or V_2 + R in V_5 = the sum of voltages of the S wave in lead V_1 or V_2 and the R wave in lead V_5.

patients by patient groups: I (control subjects), IIA (patients with aortic stenosis with normal left ventricular mass), IIB (patients with aortic stenosis with abnormal left ventricular mass) and II (A + B). The significant findings which are consistent when one compares the control group (Group I) with the total group with aortic stenosis (Group II) or with the two separate groups (IIA and IIB) are as follows:

The patients with aortic stenosis were older, with significantly higher values for electrocardiographic voltage (S wave in lead V_1 or V_2 + R wave in lead V_5), left ventricular systolic, mean diastolic and end-diastolic pressures, interventricular septal and posterior wall thickness and left ventricular mass on echocardiography, and coronary sinus flow at rest. They had a significantly smaller diastolic gradient across the aortic valve (aortic diastolic-left ventricular diastolic pressure) than did control patients [$F(2,22) = 13.29$ ($p < 0.1$)].

Angina occurred in 3 (33.3 percent) of the 9 control patients compared with 11 (68.7 percent) of the 16 patients in Group II, a statistically significant difference ($p < 0.5$) by Fisher's exact test. An ST-T "strain" pattern occurred in none of the control patients (Group I) but in 11 (73.3 percent) of 15 patients in Group II ($p < 0.01$) by Fisher's exact test. Seven of these 11 patients were taking digitalis, 1 had left bundle branch block and 3 had right bundle branch block.

Comparisons among Groups I, IIA and IIB disclosed three additional significant results: The percent change in coronary sinus flow was significantly different among groups [$F(2,22) = 7.69$, $p < 0.01$]. The percent change in coronary sinus flow in Group IIB (49 percent) was significantly smaller than that in Group I (73 percent) or Group IIA (102 percent). Aortic diastolic pressure was significantly lower in Group IIB (64.17 mm Hg) than that in Group I (72.44 mm Hg) or Group IIA (81.00 mm Hg) [$F(2,22) = 4.02$, $p = 0.03$]. The echocardiographic left ventricular internal dimension in Group IIB (46.5 mm) was significantly larger than that in Group I (41.0 mm) or Group IIA (38.4 mm) [$F(2,22) = 4.02$, $p = 0.03$].

Coronary sinus flow with hyperemia: Table II indicates the correlation of the percent change in coronary sinus flow with hyperemia (coronary vascular reserve) and 11 variables that may influence it for all 25 patients. There was a strong negative correlation be-

TABLE II

Correlations of Percent Change in Coronary Sinus Flow and 11 Other Variables

	r	p
Heart rate	+0.276	<0.18
LV-aortic systolic gradient	−0.380	<0.05*

Aortic-LV diastolic gradient	+0.643	<0.0005*
LV diastolic pressure	−0.203	<0.33
Aortic diastolic pressure	+0.636	<0.0006*
LV mass	−0.514	<0.0086*
IVS_d	−0.416	<0.0388*
$LVPW_d$	−0.407	<0.0437*
$LVID_d$	−0.412	<0.0407*

* Statistically significant ($p < 0.05$).
IVS_d = the thickness of the septum in diastole; $LVID_d$ = the dimension of the left ventricular cavity in diastole; $LVPW_d$ = the thickness of the left ventricular posterior wall in diastole; LV = left ventricular; p = probability; r = correlation coefficient.

tween percent change in flow and left ventricular mass and left ventricular-aortic systolic gradient. There was a positive correlation between the percent change in flow and the left ventricular-aortic diastolic gradient. In each case, the crucial components of these relations were the aortic systolic pressure in the left ventricular-aortic systolic gradient, and the aortic diastolic pressure in the left ventricular-aortic diastolic gradient. There was an inverse correlation between myocardial mass and percent change in coronary flow with hyperemia. A patient with severe aortic stenosis and the highest value for myocardial mass had no hyperemic reaction; this patient had the highest resting coronary flow (485 ml/min).

When the reproducibility of the coronary sinus flow data was analyzed, the coefficient of variation for flow at rest and during hyperemia was 7.1 and 9.51 percent, respectively.

Discussion

Ventricular Hypertrophy and Coronary Blood Flow

Increased myocardial oxygen delivery is normally attained by an increase in coronary blood flow, with little if any contribution from an increase in oxygen extraction.[1] In left ventricular hypertrophy secondary to pressure or volume overload, cardiac work and oxygen consumption are chronically increased with a proportional increase in coronary blood flow so that coronary blood flow and myocardial oxygen consumption per unit weight of myocardium remain normal at rest.[3–6] This increase in flow can be obtained either by dilatation of the existing coronary vasculature or by an absolute increase in the cross-sectional area of the vascular bed (neovascular growth).

Animal experiments[19–21] have suggested that left ventricular hypertrophy is associated with decreased coronary vascular reserve, determined by a failure of the coronary vascular resistance to decrease as the myocardial mass increases. Clinical studies in patients with aortic stenosis have shown an inappropriate increase in coronary blood flow secondary to isoproterenol infusion[22,23] and evidence of myocardial hypoxia (lactate production) on rapid atrial pacing.[24]

Ventricular hypertrophy and coronary vascular reserve (response to hyperemia): We studied coronary vascular reserve by analyzing the hyperemic response to selective injection of contrast agent into the coronary arteries. Sixteen patients (Group II) had left ventricular hypertrophy secondary to aortic stenosis and 9 (Group I) had chest pain syndrome with normal coronary arteries. Although the hyperemic response was similar in Groups I and II (73.3 ± 2.16 and 65.8 ± 9.11, respectively), an interesting difference was noted within Group II. Five patients (Group IIA) had aortic stenosis with a mild increase in left ventricular mass, not beyond the established upper limit of normal[16] (mean 158.8 ± 25.9 g). These patients had the highest hyperemic response in the study group (102.3 ± 9.9 percent increase in flow). Group IIB had 11 patients with a mean left ventricular mass of 308.9 ± 22.5 g; the hyperemic response in Group IIB (49.3 ± 10.4) was significantly lower than in Group IIA ($t = 4.63$, $p < 0.01$) and also significantly lower than that in Group I ($t = 2.10$, $p < 0.05$). For the entire cohort of 25 patients, left ventricular mass was inversely correlated with coronary vascular reserve ($r = -0.514$, $p < 0.0086$). The patient with the highest left ventricular mass (411 g) had a very high resting coronary sinus flow and had no further increase in flow after the injection of contrast agent, evidence suggestive of exhausted coronary vascular reserve. Coronary vascular reserve was also found to be decreased in relation to a decreased left ventricular-aortic diastolic gradient ($r = +0.643$) and to a reduced aortic diastolic pressure ($r = +0.636$); wall thickness as determined echocardiographically had an inverse relation with coronary vascular reserve ($r = -0.421$) (Table II). Thus our data support the concept that left ventricular hypertrophy is associated with a decrease in coronary vascular reserve.

Mechanisms of decreased coronary vascular volume: Our findings of a decreased coronary vascular reserve can be explained by previous experimental observations in left ventricular hypertrophy that have shown (1) the presence of vascular hyperplasia (new vessel formation),[25] although insufficient to keep a normal capillary density in the myocardium[7–9]; (2) vascular intramural changes (hypertrophy of the vessel wall) that could reduce the vascular capacitance of the resistance vessels[20,26]; (3) increased tone of the coronary vessels, related to humoral factors, myogenic constriction[27] or increased alpha-adrenergic stimulation[28]; and (4) increased myocardial tissue pressures during diastole that may increase coronary vascular resistance.[29]

Myocardial ischemia in aortic stenosis: If the hypertrophic myocardium of patients with aortic stenosis has a limited coronary vascular reserve, myocardial ischemia will occur under circumstances of increased demand. The subendocardium will tend to suffer from ischemia first[30] because the subendocardium is perfused for a shorter time in each cardiac cycle,[31] or because the oxygen consumption in the subendocardium is higher than in the subepicardium,[32] or for other yet unclear reasons. We postulate that the electrocardiographic changes of left ventricular hypertrophy traditionally called the "strain pattern"[12] may reflect the acute or chronic effects of subendocardial ischemia; in our study a "strain pattern" in the electrocardiogram was present in 9 of 11 patients in Group IIB (the other 2 patients in Group IIB had right bundle branch block). The occurrence of myocardial ischemia in patients with aortic stenosis and left ventricular hypertrophy is also suggested by the common clinical observation of angina pectoris in the absence of obstructive coronary artery disease.[33] In our study, 9 of 11 patients in Group IIB had angina pectoris. Further evidence of the tendency for ischemia to develop in patients with aortic stenosis and left ventricular hypertrophy is provided by the demonstration of lactate production during stimulation with isoproterenol.[23]

The clinical deterioration of patients with left ventricular hypertrophy may very well be related to left

ventricular failure secondary to ischemia (acute or chronic). Experimental studies[34] have proved that myocardial function deteriorates when the subendocardium is underperfused transiently and that return of normal perfusion is accompanied by recovery of left ventricular function. That underperfusion may be reversible in patients with left ventricular hypertrophy and aortic stenosis is suggested by studies done 6 months after aortic valve replacement, showing that lactate production after isoproterenol infusion no longer occurs.[23]

Possible Limitations of the Study

Coronary sinus flow measurement may not represent total left ventricular venous outflow: It has been shown that in the human heart, coronary sinus flow is highly representative of the total left ventricular efflux.[35,36] It has also been shown that coronary sinus flow as determined by the continuous thermodilution technique accurately represents total left ventricular coronary flow.[37,38] A possible source of error in the estimation of total coronary sinus flow is the fact that in some cases the posterior ventricular vein drains very near the ostium of the coronary sinus, and its flow is not included in the measurements obtained.[15] The flow measured decreases artifactually if the thermodilution catheter is advanced too far into the coronary sinus or increases artifactually if it is too close to the right atrium, especially in cases with increased right atrial pressure.[16]

These considerations would not influence the conclusions of our study since our analysis was based not on the total flow itself, but rather on the percent change in flow seen during hyperemia induced by the injection of contrast agent. The percent change should be the same for total and less than total coronary sinus flow.

Contrast agents may not induce maximal coronary vasodilation: A major limitation in our study could exist if the contrast agent produced less than maximal increase in coronary conductance, because in that case the total coronary vascular reserve could not be evaluated by this method. Existing information is controversial in this respect. The increase in coronary conductance produced by a contrast agent is equivalent to a 10 to 15 second occlusion of the coronary artery ($r = 0.86$)[39,40] and similar to the effect of an intracoronary bolus injection of adenosine triphosphate or papaverine[39] but less than the effect of a prolonged infusion of these agents.[39] The hyperemic reaction to injection of contrast agent is greater than the increased flow necessary to repay the oxygen debt, as proved by an increase in coronary sinus oxygen saturation without a change in myocardial oxygen consumption[41] and a concomitant increase in the forearm flow,[42] suggesting an important reflex component in the contrast agent-induced hyperemia.

Although the effect of contrast agents on coronary conductance may produce near-maximal vasodilation, the effects of contrast agents on cardiac and circulatory hemodynamics[43,44] may influence the hyperemic reaction qualitatively and quantitatively, and maximal coronary flow may not be obtained. Agents that increase coronary conductance without major changes in hemodynamic variables seem better suited for the study of coronary reserve in human subjects. We are currently preparing a study with such an agent, intravenous dipyridamole.

The increase in flow secondary to fast pacing (140/min through electrodes located in the coronary sinus thermodilution catheter) was measured in eight patients and found to be equal to or lower (never greater) than the hyperemic flow induced by the contrast agent. Rapid pacing produced important hemodynamic changes in patients with aortic stenosis and did not seem appropriate for the study of the coronary vascular reserve in these patients.

Even if the contrast agent had not induced maximal increase in coronary sinus flow in our study, the analysis of the directional changes observed in Groups I, IIA and IIB seem valid, as well as the analysis of the factors determining such a change (such as left ventricular dimensions and hemodynamic variables).

Dose response to contrast agent: If the hyperemic response was dose-related, the hypertrophic ventricle would receive a lower dose of contrast agent per gram of myocardium if the amount injected was always the same. In our study, patients received a bolus dose of 76 percent Renografin, sufficient to opacify clearly the entire left coronary artery (5 to 10 ml).

A similar hyperemic reaction has been reported when 3 to 10 ml of contrast agent is injected.[39,45] In our study, injection of 1 to 2 ml of contrast agent was associated with a minimal or absent hyperemic response. Five versus 10 ml injections were tested on repeated random measures in 10 patients. Calculations of the resting and hyperemic coronary sinus flow were done blindly in these cases, without knowledge of the dose injected. There was no statistically significant difference between the hyperemia (percent change) induced by the two volumes of injectate (paired $t = 1.86$, difference not significant). It seems unlikely that the results obtained in our study were artifactually influenced by a dose-response effect.

Determinants of coronary flow not studied: Important determinants of coronary flow, such as the duration of systole and diastole, were not specifically analyzed in this study. These may have a major influence on coronary vascular reserve.

Control group: Nine patients with chest pain syndrome found to have normal coronary arteries and normal left ventricular function served as control subjects in our study. Our results showed that this group had a lower coronary reserve than that of patients with aortic stenosis and mild or no hypertrophy (Group IIA) ($t = -2.04$, $p = 0.06$). Preliminary information in the form of an abstract[46] proposes that a decrease in coronary vascular reserve may be related to the pathogenesis of chest pain in these patients. On the other hand, patients in an initial phase of left ventricular hypertrophy

(Group IIA) may have an increased coronary reserve capacity.

A decreased coronary vascular reserve in Group I may explain why we found no difference in the coronary reserve of Groups I versus II. However, our conclusions regarding the correlation of the coronary vascular reserve with other variables (such as left ventricular mass and hemodynamic variables) are still valid, and appear most relevant when comparing Groups IIA and IIB. Further studies appear necessary, in which a group with "normal" coronary vascular reserve can be analyzed and used as a control group. A truly normal group may be difficult to obtain because such patients rarely undergo diagnostic cardiac catheterization.

Implications: Our study shows that patients with left ventricular hypertrophy secondary to aortic stenosis have a decrease in coronary vascular reserve, proportional to the increase in left ventricular mass and the decrease in left ventricular-aortic diastolic gradient and in aortic diastolic pressure. We speculate that this decrease in coronary vascular reserve may be related to the ischemic components of left ventricular hypertrophy. Further investigation seems necessary to clarify and expand the findings of this study.

Acknowledgment

We express our gratitude to Timothy Last for his expert and diligent secretarial assistance in the preparation of this manuscript.

Electrocardiographically synchronized radionuclide angiography was performed before, during and after induced paroxysmal supraventricular tachycardia in 13 patients. Data were acquired with a computer-interfaced Anger camera in a left anterior oblique projection. No data were acquired during tachycardia until tachycardia had been sustained for 1 minute. Patients ranged in age from 20 to 64 years (mean ± standard deviation 42 ± 14.5). Three patients had organic heart disease and 10 did not. Baseline and tachycardia heart rates (beats/min) were 59 to 99 (73 ± 11) versus 141 to 228 (157 ± 22). Baseline and tachycardia left ventricular measurements (mean ± standard error) were as follows: ejection fraction 64 ± 2 versus 62 ± 4 percent (not significant), ejection rate 3.0 ± 0.1 versus 4.3 ± 0.4 mean ventricular counts/s ($p < 0.001$), normalized end-diastolic counts 72.7 ± 7.8 versus 48.7 ± 6.7 × 10^3 counts ($p < 0.001$), normalized stroke counts 37.1 ± 3.4 versus 23.3 ± 2.7 × 10^3 counts ($p < 0.001$) and normalized count cardiac output 2,717.5 ± 273.0 versus 3,620.2 ± 403.7 × 10^3 counts/min ($p < 0.005$). Although ejection fraction for the whole group did not change significantly, it decreased during tachycardia by 5 percentage points or more in five patients. These were the three patients with heart disease and the two normal patients with the fastest heart rate during tachycardia (228 and 214 beats/min, respectively).

In summary, paroxysmal supraventricular tachycardia was characterized by a marked decrease in left ventricular end-diastolic and stroke volumes but increased ejection rate and cardiac output without significant change in ejection fraction. Heart disease or rapid heart rate during tachycardia appeared to have a deleterious effect on ejection fraction.

Paroxysmal supraventricular tachycardia is a common arrhythmia, often accompanied by symptoms and signs of hemodynamic embarrassment. However, only few data are available concerning its hemodynamics. There exist several case reports of hemodynamic data obtained when tachycardia occurred fortuitously in the course of cardiac catheterization.[1–7] In addition, two larger series were recently reported concerning tachycardia induced under controlled conditions, so that planned hemodynamic observations could be made.[8,9] In all of the aforementioned studies, the resulting data consisted of blood pressures, atrial pressure tracings, stroke volume and cardiac output with a major emphasis on the period immediately after the onset of tachycardia and less emphasis on steady state. There are a few direct data on left ventriclar volume, ejection fraction and wall motion during tachycardia.

The development of nuclear angiography has made possible evaluation of these measurements of left ventricular function both at rest and during exercise.[10–12] In this study, we report nuclear angiographic findings in 13 patients in whom imaging was performed before, during and after sustained paroxysmal supraventricular tachycardia.

Methods

Study patients: The following criteria were used in the selection of patients for this study: (1) history of documented recurrent paroxysmal supraventricular tachycardia, (2) ability to induce and terminate sustained tachycardia reliably

in the electrophysiology laboratory, (3) presence of a radiofrequency pacemaker (2 patients) or temporary pacing catheter (11 patients) during chronic drug study enabling induction and termination of tachycardia in the nuclear medicine laboratory, (4) signing of informed consent. No attempt was made to restrict the study to patients with the presence or absence of a specific symptom complex during tachycardia. The mechanism of tachycardia was established during intracardiac electrophysiologic study using previously published criteria.[13]

Thirteen patients, aged 20 to 60 years (mean ± standard deviation, 42 ± 14.5) had radionuclide angiography during tachycardia; 7 were women and 6 were men. Ten of the 13 patients had no evident organic heart disease, 1 patient (Case 11), had aortic valve insufficiency, 1 (Case 12) had corrected transposition of the great vessels with a ventricular septal defect and one (Case 13) had restrictive cardiomyopathy. Eleven patients were taking no cardioactive medications during the study. One patient (Case 11) was taking propranolol, 40 mg orally three times daily, and one (Case 6) was taking disopyramide, 300 mg orally every 6 hours. Neither drug interfered with induction of tachycardia.

The mechanism of the tachycardia as defined by intracardiac electrophysiologic study was atrioventricular (A-V) reentrance using an anomalous pathway for retrograde conduction in seven patients, A-V nodal reentrance in five and atrial reentrance in one.

Nuclear angiography: Electrocardiographically gated, equilibrium nuclear angiography was performed using an in vivo red blood cell labeling method with 18 to 25 mCi of technetium-99m.[14] A large field Anger camera (Searle LFOV) was positioned for a left anterior oblique view with the patient supine. Data were recorded and analyzed on an Informatek Simis 3 computer.

A baseline study was acquired while the patient had sinus rhythm. With this completed, tachycardia was induced by cardiac stimulatory techniques. No data were acquired for the 1st minute after induction of tachycardia to allow for stabilization of cycle length and to avoid previously described early hemodynamic effects[8] that are not prolonged enough for assessment by this technique. With no change in the position of the patient or the camera, a complete study was performed during tachycardia, after which tachycardia was terminated with pacing. One patient had a second study during tachycardia after atropine, 1 mg intravenously. When each patient's pulse and blood pressure had returned to baseline values (within 5 to 10 minutes), a post-tachycardia study was performed (10 of 13 patients). Again, the position of the patient and camera were unchanged.

Data were acquired before, during and after tachycardia for a total of 5 to 10 minutes for each of the three studies. Blood pressure (cuff method), the electrocardiogram and symptoms were monitored and recorded during the three data acquisition periods.

Processing of data: The equilibrium gated acquisition was stored in 16 frames of 64 by 64 matrix resolution. Ejection fraction was calculated using a program based on three regions of interest: end-diastole, end-systole and perisystolic background. The end-diastolic region of interest is drawn semiautomatically, with the septum and valve plane hand-drawn using the stroke volume image (end-diastole minus end-systole) as a guide. This procedure aids both reproducibility and exclusion of the left atrium from the region of interest. The protocol was previously described for first transit studies[15] and was validated for gated studies in this laboratory (for 17 patients with an ejection fraction of 26 to 81 percent the correlation coefficient with biplane contrast angiography was 0.85 [$p < 0.0001$]). Each study was processed independently, so that changes in ventricular volume and background level were taken into account. From the interpolated time-activity curve obtained in this protocol, the left ventricular ejection rate was calculated according to the method of Marshall et al.[16] and expressed in units of mean ventricular counts/s. Regional wall motion was evaluated by consensus among three experienced observers using the display of superimposed end-diastolic and end-systolic contours and three functional images: the stroke volume image, the paradox image (end-systole minus end-diastole) and the regional ejection fraction image.

Relative end-diastolic volumes (*end-diastolic counts*) were calculated using the total counts in the left ventricular region of interest at end-diastole after background correction. Relative stroke volumes (stroke counts) were calculated using only the end-diastolic region of interest and subtracting its contents at end-systole from its contents at end-diastole. No background subtraction was necessary for this calculation because only one region was used. Relative cardiac output (count cardiac output) was defined as the product of stroke counts times heart rate.

For comparison of the three studies on each patient, the end-diastolic counts must be normalized to the same counting time and corrected for decay. The counting time is the product of the frame length and the number of cycles acquired in the study, but a simple normalization can be made by using as reference the number of counts contained in the whole field of view in the end-diastolic frame of the baseline acquisition. If the subsequent acquisitions (during and after tachycardia) differ in number of cycles or frame duration, this difference will be reflected in the number of counts in the whole field of view. The correction factor calculated in this way also includes the decay factor, because decay tends to decrease the total number of counts during the second and third acquisitions.

This method of normalization could be validated for the last four patients studied (in whom the exact number of cycles acquired was available) by comparison with normalization to exact counting time with correction for decay. For these four patients, there was less than a 5 percent difference in the two normalization methods. It is clear that neither method allows comparison of volumes between patients.

Analysis of data: Statistical analysis was done using Student's *t* test for paired values (two-tailed). Tachycardia and post-tachycardia values for end-diastolic counts, stroke counts and count cardiac output were calculated for each patient as a percent of baseline values. This calculation was used for graphic and qualitative analysis only.

Results

Hemodynamics: Baseline Versus Tachycardia (Table I)

Heart rate (Fig. 1): Baseline heart rates ranged from 59 to 99 (mean ± standard error of the mean 73 ± 11) beats/min. Heart rates during tachycardia ranged from 141 to 228 (mean 157 ± 22) beats/min. Baseline systolic blood pressure ranged from 90 to 130 (mean 113 ± 14) mm Hg. During tachycardia, systolic blood pressure ranged from 72 to 130 (mean 102 ± 22) mm Hg (difference not significant [NS]). Only two patients, one with organic heart disease (Case 12) and one with a heart rate during tachycardia of 228 beats/min (Case 8), had a marked decrease in systolic blood pressure (from 105 to 82 and from 118 to 74 mm Hg, respectively). For these two patients, the cuff blood pressure during tachycardia was only palpable so no diastolic reading is available.

For the remaining patients, diastolic blood pressure ranged from 55 to 80 (mean 68 ± 8) during the baseline period versus 60 to 95 (mean 77 ± 13) mm Hg during tachycardia.

Ejection fraction (Fig. 1): For the entire group, baseline ejection fraction ranged from 53 to 76 percent (mean ± standard error of the mean 64 ± 2). During tachycardia, ejection fraction ranged from 37 to 76 percent (mean 62 ± 4) (NS). Four patients (and one additional patient after atropine) had a decrease in ejection fraction during tachycardia of more than 5 percentage points (see later). No patient had an increase in ejection fraction during tachycardia of more than 5 percentage points.

Baseline ejection rate for the entire group ranged from 2.1 to 4.9 (mean 3.0 ± 0.2) in units of mean ventricular counts/s. During tachycardia, ejection rate ranged from 1.7 to 7.0 (mean 4.3 ± 0.4) ($p < 0.001$) (Fig. 1). Ejection rate decreased during tachycardia in only two patients (see later).

End-diastolic ventricular volume (Fig. 2 and 3): Baseline relative end-diastolic volume, as estimated by normalized end-diastolic counts, ranged from 10.7 to 122.0 (mean 72.7 ± 7.8) thousand counts. During tachycardia, end-diastolic counts decreased in all patients to a range of 5.6 to 100.9 (48.7 ± 6.7) thousand counts ($p < 0.001$). The wide range of values for end-diastolic counts (as well as for stroke counts and count cardiac output) reflects the lack of standardization of baseline acquisition time early in the series. Thus comparison of normalized numbers of end-diastolic counts, stroke counts and count cardiac output, while appropriate for the three studies in the same patient, is not appropriate for comparing one patient with another. Expressed as a percent of baseline, normalized end-diastolic counts during tachycardia ranged from 43 to 91 percent (median 65 percent).

Stroke volume (Fig. 2 and 3): Baseline relative stroke volume, as estimated by normalized stroke counts, ranged from 5.4 to 52.6 (mean 37.1 ± 3.4) thousand counts. During tachycardia, stroke counts decreased in all patients to a range of 2.8 to 39.6 (mean 23.3 ± 2.7) thousand counts ($p < 0.001$). Expressed as a percent of baseline value, normalized stroke counts during tachycardia ranged from 47 to 89 percent, median 50 percent).

Cardiac output (Fig. 2): Baseline relative cardiac output, as estimated by normalized count cardiac output, ranged from 348 to 3,822 (mean 2,717.5 ± 273.0) thousand counts. During tachycardia, count cardiac output increased, although modestly, in all patients to a range of 441 to 6,091 (mean 3,620.2 ± 403.7) thousand counts ($p < 0.005$). Expressed as a percent of baseline value, normalized count cardiac output during tachycardia ranged from 105 to 182 percent (median 132 percent).

Wall motion: All the patients without organic heart disease had normal wall motion at rest and during tachycardia. One of three patients with organic heart disease (Case 12, with a previously repaired ventricular septal defect) had markedly abnormal septal motion

* Measured in units of mean ventricular counts/s.
Base = baseline; OHD = organic heart disease; Post = after tachycardia; PSVT = paroxysmal supraventricular tachycardia; + = present; − = absent.

that persisted during tachycardia. A second patient with heart disease (Case 11) had no abnormality of wall motion at rest or with tachycardia. The third patient with heart disease (Case 13) had normal wall motion at rest but septal akinesia with tachycardia.

Tachycardia after atropine (Table II): One patient (Case 7) was given atropine, 1 mg intravenously, after the tachycardia study was completed. Tachycardia was reinduced and a second tachycardia study was acquired to reflect the faster heart rate after atropine (214 versus 170 beats/min). Ejection fraction during tachycardia after atropine decreased, both in relation to tachycardia before atropine (55 versus 70 percent) and in relation to the baseline value (55 versus 65 percent).

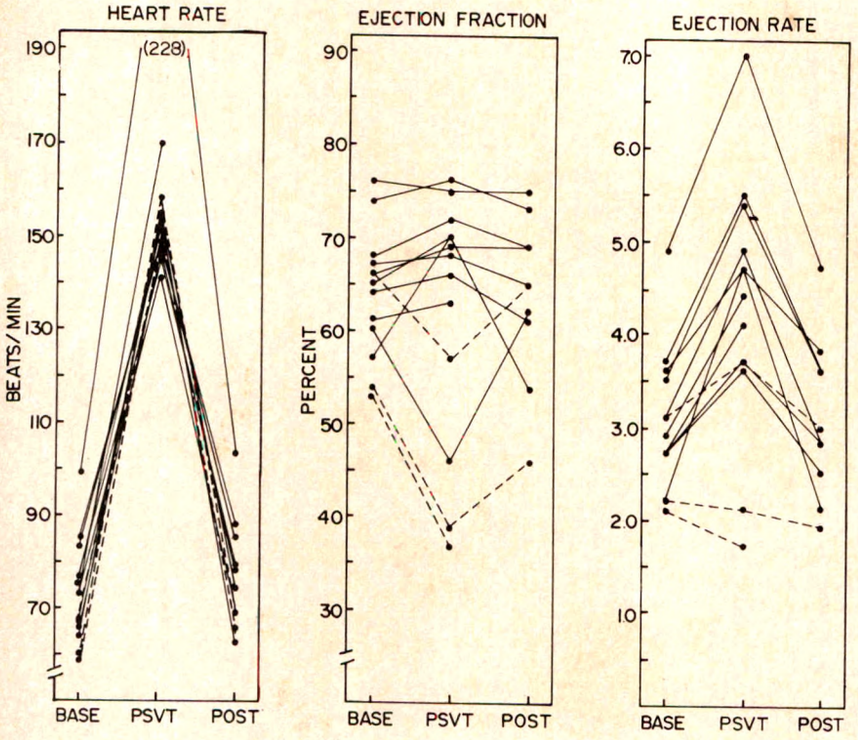

FIGURE 1. Heart rate (beats/min), ejection fraction (percent) and ejection rate (mean ventricular counts/s) before (BASE), during and after (POST) induced sustained paroxysmal supraventricular tachycardia (PSVT). Each **closed circle** represents one patient. The **dashed lines** identify the three patients with organic heart disease (Cases 11, 12 and 13).

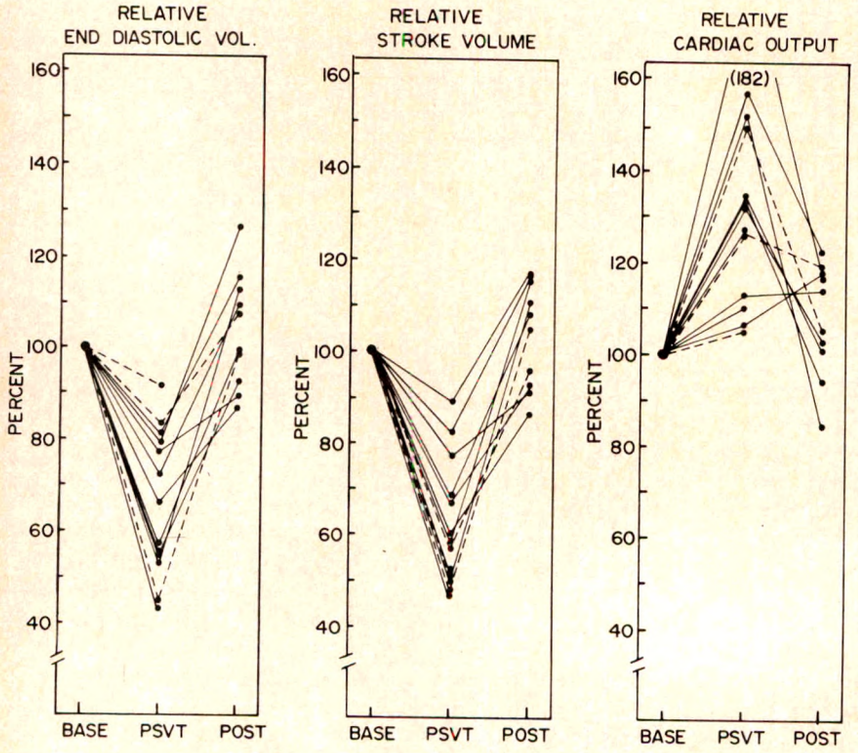

FIGURE 2. Relative end-diastolic volume (VOL.), stroke volume and cardiac output as measured by normalized end-diastolic counts, stroke counts and count cardiac output. Baseline values are defined as 100 percent. Paroxysmal supraventricular tachycardia (PSVT) and post-tachycardia values are expressed as a percent of baseline value (see text). Each **closed circle** represents one patient; the **dashed lines** identify the three patients with heart disease.

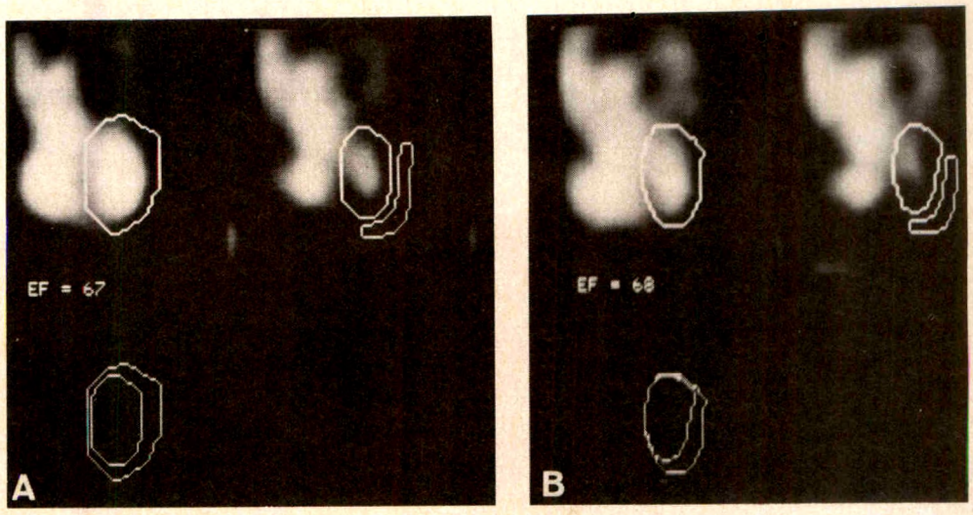

FIGURE 3. Case 5. Example of nuclear angiographic studies in a patient with no organic heart disease. **A,** baseline images; **B,** during paroxysmal supraventricular tachycardia. The end-diastolic frame (**upper left**), end-systolic frame and background region of interest (**upper right**), and superimposed end-diastolic and end-systolic regions of interest (**lower left**) are shown for each study. EF = ejection fraction (percent).

Ejection rate was comparable during tachycardia with and without atropine (4.2 versus 4.1). Normalized end-diastolic counts during tachycardia after atropine were greater than during tachycardia before atropine (36.4 versus 25.6 thousand counts) but still substantially decreased from the baseline value (59.9 thousand counts). Normalized stroke counts were decreased further during tachycardia after atropine (11.7 versus 14.5 thousand counts). Normalized count cardiac output was unchanged (2,499.3 versus 2,472.9 thousand counts).

Hemodynamics: Baseline Versus Post-Tachycardia (Table I)

Post-tachycardia studies were performed in 11 patients. However, one patient had received atropine for a second tachycardia study (see earlier) and therefore the post-tachycardia study in that patient did not represent a return to baseline condition. Thus 10 patients are included in the following analysis.

There was no statistically significant difference in heart rate or systolic or diastolic blood pressures in the baseline and post-tachycardia studies. This would be expected from the study design. In addition, there was no statistically significant difference in ejection fraction, ejection rate, end-diastolic counts, stroke counts or count cardiac output. Wall motion assessed in the post-tachycardia period was comparable with the baseline state in all patients.

Effect of Heart Disease and Rapid Heart Rate

Ejection fraction: Because only three patients had underlying organic heart disease and only two had a relatively rapid heart rate during tachycardia, we considered statistical analysis of these variables inappropriate. However, there were interesting features of the hemodynamic response to tachycardia in these five patients. Ejection fraction decreased by more than five percentage points during tachycardia in five patients. These were the three patients with organic heart disease (Cases 11, 12 and 13) and the two patients with the fastest heart rates during tachycardia (228 beats/min [Case 8] and 214 beats/min [Case 7, after atropine]). The decrease in ejection fraction in these five patients was 9, 15, 16, 14 and 10 percentage points, respectively. The third fastest heart rate during tachycardia was only 170 beats/min (Patient 7 before atropine) and was associated with an increase in ejection fraction over baseline (70 versus 65 percent). The three patients with organic heart disease had a marked decrease in ejection fraction during tachycardia despite a normal or borderline baseline ejection fraction (66, 54 and 53 percent, respectively).

TABLE II

Nuclear Angiographic Data Before and After Atropine in Patient 7

		Paroxysmal Supraventricular Tachycardia	
	Baseline	Before Atropine	After Atropine
Heart rate	73	170	214
Ejection fraction (%)	65	70	55
Ejection rate (mean ventricular counts/s)	2.7	4.1	4.2
End-diastolic counts ($\times 10^3$)	59.9	25.6	36.4
Stroke counts ($\times 10^3$)	30.8	14.5	11.7
Count cardiac output ($\times 10^3$)	2,247.7	2,472.9	2,499.3

Ejection rate and stroke volume: In addition, ejection rate decreased in only two patients during tachycardia (Cases 12 and 13). Both patients had organic heart disease. Stroke counts during tachycardia were decreased to less than 50 percent of the baseline value for five tachycardia studies in four patients. These were the patient (Case 8) with the fastest tachycardia (49 percent), the patient with the next fastest tachycardia (Case 7) both before and after atropine (47 and 38 percent, respectively) and two of the three patients (Cases 11 and 13) with organic heart disease (both 48

percent). The next two tachycardia studies with lowest stroke counts in relation to the baseline value were in one patient (Case 4) with neither a fast heart rate during tachycardia nor heart disease (52 percent) and in the third patient (Case 12) with organic heart disease (58 percent). It therefore appears that the presence of underlying organic heart disease or rapid heart rate during tachycardia greatly modified the hemodynamic response to tachycardia in the small number of patients studied.

Discussion

Previously reported studies: A number of reports[1–7] of single cases and small series have appeared concerning the effect of paroxysmal supraventricular tachycardia (often occurring fortuitously in the course of cardiac catheterization) on hemodynamic variables. In general, this tachycardia has been said to reduce blood pressure, stroke volume and cardiac output markedly. In addition, several investigators[3,4] noted large atrial waves in both the right atrial and pulmonary capillary wedge pressure tracings, most likely reflecting atrial systole against closed A-V valves. In one study,[4] a tendency was described for hemodynamic variables to be most abnormal at the onset of tachycardia and then to return gradually toward normal within the 1st minute of tachycardia. It should be noted that in the 14 patients reported on in the studies just cited,[1–7] the average heart rate during tachycardia was 187 beats/min. Most observations tended to be made very soon after the onset of tachycardia.

Two larger series of patients with hemodynamic measurements during paroxysmal supraventricular tachycardia have been reported.[8,9] Goldreyer et al.[8] studied eight patients with A-V nodal reentrant tachycardia who had reported disabling symptoms during tachycardia. The average heart rate during tachycardia was 183 beats/min. Tachycardia induced during cardiac catheterization was accompanied by a decrease in mean systolic arterial pressure from 141 to 99 mm Hg and a decrease in cardiac index from 3.6 to 2.2 liters/min per m^2. As in previous case reports, the observations of Goldreyer et al. were made early after the onset of tachycardia. Emphasis was placed on the first 60 to 90 seconds after induction of arrhythmia, and the observations of Sanders and Ord[4] of severe hemodynamic embarrassment at the onset of tachycardia were confirmed.

Schlepper et al.[9] reported hemodynamic observations during paroxysmal supraventricular tachycardia in 10 patients with a mean heart rate of 176 beats/min during tachycardia. Measurements were taken approximately every 2 minutes until tachycardia was terminated at 10 minutes. Expressed as a percent of baseline, mean aortic pressure varied from 68 percent at the onset of tachycardia to 92 percent in the 9th minute. Cardiac index ranged from 67 to 82 percent of baseline value and stroke volume from 36 to 41 percent. Measurements of maximal first derivative of left ventricular pressure (dP/dt) ranged from 60 percent of the baseline value at the onset of tachycardia to 107 percent in the 9th minute.

There is no previous study of hemodynamics during sustained arrhythmia using radionuclide studies. Measurement of ejection fraction and ejection rate and evaluation of wall motion by nuclear methods are well established procedures. Absolute ventricular volume measurements at rest and during exercise have also been described recently,[11,12] as have measurements of relative cardiac output under similar conditions.[17]

Methodology: In this study the patient served as his or her own control, and thus a relative method could be used for volume and output measurements. A prerequisite for this relative method is a normalization procedure. The one we used compensates for variable acquisition time, variable frame duration and radioactive decay. To minimize the errors in calculating stroke counts and count cardiac output, the end-diastolic region of interest alone was used so that stroke counts could be calculated without the need for background correction. This protocol allows comparison of baseline and tachycardia studies, even when tachycardia terminates spontaneously (as in Patients 7 and 10) before a preset number of counts is acquired.

Hemodynamic response to paroxysmal tachycardia: In our study, paroxysmal supraventricular tachycardia was characterized by a marked decrease in stroke volume. This finding is in agreement with previously reported results.[8,9] However, we found a modest increase in cardiac output (median value 132 percent of baseline) in contrast to the decrease reported previously. There are two possible reasons for this discrepancy. First, in most previous studies measurements were made early after the onset of tachycardia and reflect the more severely abnormal hemodynamics during this period. Second, the average heart rate during tachycardia in our study (157 beats/min) is somewhat slower than that of most previous studies. Of the two patients in the study by Goldreyer et al.[8] with a heart rate of less than 170 beats/min during tachycardia, one had a modest increase in cardiac index (4.1 to 4.3 liters/min per m^2) and the other had only a modest decrease (3.5 to 3.1 liters/min per m^2). The marked decrease in end-diastolic volume and the lack of change in ejection fraction and wall motion have not been previously described because these measurements would have necessitated performance of ventricular angiography during tachycardia.

Effect of very rapid heart rate and organic heart disease: In our study, a very rapid heart rate or the presence of underlying heart disease seemed to modify the hemodynamic response to paroxysmal supraventricular tachycardia. All three patients with organic heart disease and the two patients with the fastest heart rates during paroxysmal tachycardia had a marked decrease in ejection fraction. The decrease in stroke volume during tachycardia in relation to the baseline value also tended to be greatest in these patients. Although it is not surprising that the hemodynamic consequences of tachycardia should be more severe under these circumstances, it has not been demonstrated previously. Confirmation of these findings during tachycardia must await observations in larger groups of such patients. Ricci et al.[18] recently demonstrated a

decrease in ejection fraction during rapid atrial pacing in patients with heart disease.

Comparison with atrial pacing and exercise: Comparison of the hemodynamic consequences of paroxysmal supraventricular tachycardia with those of rapid heart rates achieved by atrial pacing and exercise may be instructive. Rushmer[19] reviewed previous data showing that stroke volume changed very little during exercise in dogs and human beings. He confirmed this observation in 37 dogs and compared the response to rapid atrial pacing by driving an atrial pacemaker at the dog's tape-recorded heart rate during exercise. During pacing, end-diastolic diameter and stroke volume decreased greatly. Since Rushmer's report, several studies[20–23] have confirmed maintenance of end-diastolic dimensions with little change or even an increase in stroke volume during exercise. These events result in a large increase in cardiac output. Using nuclear angiography, Slutsky et al.[12] observed an increase in ejection fraction during exercise from 67 to 80 percent with no significant change in end-diastolic volume (15.8 versus 15.2 volume units), implying an increase in stroke volume. Sorensen et al.[17] observed that count cardiac output increased an average of almost 400 percent during exercise in nine normal men.

In contrast, rapid atrial pacing consistently caused a decrease in end-diastolic volume and stroke volume with little if any resulting change in cardiac output.[19,24–30] There has been as yet no study of the hemodynamics of rapid atrial pacing using nuclear angiography. Wisenberg et al.[31] reported little change in ejection fraction or cardiac output (+4 percent), with decreases in end-diastolic (−29 percent) and stroke (−37 percent) volumes at heart rates of up to 100 beats/min. It is clear, then, that the hemodynamic features of paroxysmal supraventricular tachycardia are similar to those of rapid atrial pacing and not those of exercise.

Eighty-eight patients with preexcitation were studied to determine how 30 patients with documented spontaneous paroxysmal atrial fibrillation differed from 58 patients without this arrhythmia. Inducible reentrant tachycardia was present in 23 (77 percent) of the 30 patients with, versus 28 (48 percent) of the 58 patients without, atrial fibrillation ($p < 0.025$). Heart disease was present in 13 (43 percent) of the 30 patients with, versus 15 (26 percent) of the 58 patients without, atrial fibrillation (not significant). Inducible reentrant tachycardia or heart disease, or both, were present in 29 (97 percent) of the 30 patients with, versus 34 (59 percent) of the 58 patients without, atrial fibrillation ($p < 0.0005$).

Of 51 patients with inducible reentrant tachycardia, 23 patients with atrial fibrillation did not differ from 28 patients without this arrhythmia with respect to clinical features and atrial, sinus nodal, or anomalous pathway properties, or cycle length of induced reentrant tachycardia. Spontaneous degeneration of induced reentrant tachycardia to atrial fibrillation was observed in 6 (26 percent) of 23 patients with, versus none of 28 patients without, atrial fibrillation ($p < 0.025$).

In summary, patients with preexcitation and documented spontaneous paroxysmal atrial fibrillation almost always have inducible reentrant tachycardia or heart disease, or both. It is likely that in many patients with inducible reentrant tachycardia, spontaneously occurring reentrant tachycardia relates to induction of atrial fibrillation. However, it is unclear why some patients with inducible reentrant tachycardia have atrial fibrillation and others do not. In many patients with organic heart disease, atrial fibrillation could relate to hemodynamic changes.

Some patients with preexcitation have recurrent paroxysmal supraventricular tachycardia or paroxysmal atrial fibrillation, or both.[1–4] The former arrhythmia usually reflects the occurrence of atrioventricular (A-V) reentrance, utilizing normal and anomalous A-V pathways.[5–8] Induction of A-V reentrant paroxysmal tachycardia reflects the presence of measurable normal and anomalous pathway properties.[8] In contrast, the pathophysiology of paroxysmal atrial fibrillation in patients with preexcitation is less clear. Several groups of investigators[9–11] have suggested that in some patients with preexcitation, paroxysmal atrial fibrillation might result from A-V reentrant tachycardia.

In this study, we attempted to elucidate further the pathophysiology of paroxysmal atrial fibrillation in preexcitation, by attempting to measure clinical and electrophysiologic variables, in a series of 88 patients with preexcitation. We attempted to determine how patients with preexcitation who have documented episodes of spontaneous paroxysmal atrial fibrillation differ from those without this arrhythmia.

Methods

Patient selection: Criteria for inclusion in the study were: (1) evidence of typical preexcitation in one or more electrocardiograms during normal sinus rhythm, and (2) referral to our laboratory for cardiac electrophysiologic studies (see later). Both symptomatic and asymptomatic patients were studied with use of a protocol approved by our institutional human investigation committee.

This study was supported in part by Institutional Training Grant HL 07387 and Research Grants HL 18794 and HL 23566 from the National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, Maryland and a grant from the Eleanor B. Pillsbury Resident Trust Fund. Manuscript received August 27, 1980; revised manuscript received October 13, 1980, accepted October 24, 1980.

Address for reprints: Robert A. Bauernfeind, MD, Cardiology Section, University of Illinois Hospital, P.O. Box 6998, Chicago, Illinois 60680.

Eighty-eight patients referred to our institution between December 1972 and February 1980 fulfilled these criteria. Sixty-seven were male and 21 female; their ages ranged from 12 to 67 years (mean ± standard deviation 36 ± 15). Thirty of the 88 patients had had one or more electrocardiographically documented episodes of spontaneous paroxysmal atrial fibrillation, the other 58 patients had not had documented atrial fibrillation. Nineteen of the 88 patients had intermittent preexcitation (one or more electrocardiograms failed to show preexcitation during normal sinus rhythm).

Clinical evaluation: Electrocardiograms of documented arrhythmias were obtained from referring physicians and hospital emergency rooms. Atrial fibrillation and paroxysmal supraventricular tachycardia were diagnosed using standard electrocardiographic criteria.[12] The presence or absence of organic heart disease was determined by history, physical examination, electrocardiogram, chest roentgenogram and (after July 1974) echocardiogram. Diagnostic cardiac catheterization was performed when clinically indicated. Standard criteria were used to diagnose and classify organic heart disease.[13]

Electrophysiologic studies: These studies were performed in the postabsorptive, nonsedated state after cardioactive drugs had been discontinued for at least 48 hours. Informed written consent was obtained from all patients. The electrophysiologic protocol performed has previously been reported[4] and included the following: (1) recording of basic conduction intervals during regular sinus rhythm; (2) incremental pacing from several atrial sites; (3) atrial extrastimulus testing during sinus rhythm and at an atrial paced cycle length of 600 ms; (4) incremental ventricular pacing; and (5) ventricular extrastimulus testing. No systematic attempt was made to induce atrial fibrillation in this series of patients.

Patients were assessed for ability to have induced A-V reentrant tachycardia, in which the normal conduction system is utilized for anterograde conduction and the anomalous pathway is utilized for retrograde conduction (orthodromic variety),[7,8] or in which the anomalous pathway is utilized for anterograde conduction and the normal pathway is utilized for retrograde conduction (antedromic variety).[14–16] Criteria employed by us and others for diagnosis of these varieties of paroxysmal tachycardia have also been reported elsewhere.[4,16] Patients were considered to have inducible A-V reentrant tachycardia when one or more modalities of cardiac stimulation (see earlier) resulted in A-V reentrant tachycardia that was sustained for 2 or more minutes (in the absence of atropine or isoproterenol).

In the patients who had inducible tachycardia, the following were noted: (1) cycle length of induced tachycardia; (2) the effect (or lack of effect) of occurrence of functional bundle branch block on cycle length of induced tachycardia[17,18]; (3) atrial activation sequence during induced tachycardia (determined by recording from multiple atrial sites)[7,19,20]; and (4) occurrence of spontaneous (not associated with cardiac stimulation) conversion of induced tachycardia to atrial fibrillation.[10,11] Patients were considered not to have inducible A-V reentrant tachycardia when all modalities of cardiac stimulation failed to produce A-V reentrant echo beats or produced only single echo beats or brief episodes of self-terminating tachycardia.

Anomalous pathway location was determined by application of combinations of the following observations: (1) QRS configuration during regular sinus rhythm[21]; (2) QRS configuration during maximal preexcitation (obtained by pacing the atria at rates faster than sinus heart rate)[21]; (3) the atrial pacing site that resulted in the shortest stimulus-delta wave interval[22]; (4) atrial activation sequence during ventricular pacing and induced A-V reentrant tachycardia[7,19,20]; and (5) the effect (or lack of effect) of functional bundle branch block on cycle length of induced A-V reentrant tachycardia.[17,18]

Corrected sinus nodal recovery time[23] *and calculated sinoatrial conduction time*[24] *were defined and measured as previously described.* High right atrial refractory periods were determined at a paced cycle length (A_1-A_1) of 600 ms. The atrial functional refractory period was defined as the shortest A_1-A_2 interval achieved. The atrial effective refractory period was defined as the longest S_1-S_2 interval at which the extrastimulus (S_2) failed to produce an atrial response (A_2). Dispersion of atrial effective refractory period was defined as the difference between atrial effective refractory periods measured in the high right atrium and in the coronary sinus at a paced cycle length of 600 ms.[25]

Statistical analyses: Comparisons between the two groups of patients with respect to the presence or absence of specific attributes were made by 2 by 2 chi-square analysis with Yates' correction. Comparisons between the two groups of patients with respect to anomalous pathway location were made by 3 by 2 chi-square analysis. Comparisons between the two groups of patients with respect to numerical data were made by *t* test for unpaired data.

Results

Characteristics of study group: Thirty (34 percent) of the 88 study patients had electrocardiographically documented episodes of spontaneous paroxysmal atrial fibrillation before referral (12 patients had had one episode, and 18 patients had had two or more episodes). Mean ventricular rates during atrial fibrillation in these patients ranged from 130 to 300 beats/min (mean ± standard deviation, 204 ± 44), and the shortest R-R intervals ranged from 150 to 410 ms (223 ± 68). Twenty-one of these patients had required direct current cardioversion on one or more occasions. The other 58 (66 percent) of the 88 study patients did not have documented atrial fibrillation.

Before referral, 33 (38 percent) of the 88 study patients had electrocardiographically documented episodes of spontaneous paroxysmal supraventricular tachycardia, whereas 55 (62 percent) did not. During electrophysiologic studies, 51 (58 percent) of the 88 study patients had inducible A-V reentrant tachycardia (orthodromic variety in 49 patients and antedromic variety in 2 patients), whereas 37 (42 percent) did not. Twenty-eight (32 percent) of the 88 patients had organic heart disease (Table I), whereas 60 (68 percent) did not.

Comparisons of patients with and without spontaneous paroxysmal atrial fibrillation: We attempted to determine how the 30 patients with documented spontaneous paroxysmal atrial fibrillation differed from the 58 patients without documented atrial fibrillation. The two groups did not differ with respect to age: The mean age of each group was 36 years. The groups also did not differ significantly with respect to sex: Twenty-five (83 percent) of the 30 patients with documented atrial fibrillation and 42 (72 percent) of the 58 patients without atrial fibrillation were male. Of the 30 patients with documented atrial fibrillation, 9 (30 percent) had left free wall, 15 (50 percent) had septal or paraseptal and 6 (20 percent) had right free wall anomalous pathways, whereas of the 58 patients without atrial fibrillation, 17 (29 percent) had left free wall, 18

TABLE I

Associated Heart Disease in 88 Patients with Wolff-Parkinson-White Syndrome

	Patients With Atrial Fibrillation (30 patients)	Patients Without Atrial Fibrillation (58 patients)
Coronary artery disease	1	2
Hypertensive heart disease	1	5
Cardiomyopathy	5	3
Valvular heart disease	4	2
Cor pulmonale	0	1
Congenital heart disease		
Ebstein's anomaly	2	0
Atrial septal defect	0	1
Corrected transposition	0	1
Total	13	15

(31 percent) had septal or paraseptal, and 23 (40 percent) had right free wall anomalous pathways (difference not significant [NS]).

Relation of paroxysmal atrial fibrillation to spontaneous and inducible paroxysmal tachycardia and to organic heart disease (Table II): We attempted to determine whether the 30 patients with documented episodes of spontaneous paroxysmal atrial fibrillation differed from the 58 patients without documented atrial fibrillation with respect to the occurrence of spontaneous paroxysmal supraventricular tachycardia, the presence of inducible A-V reentrant tachycardia or the presence of organic heart disease. Before referral, 9 (30 percent) of the 30 patients with and 24 (41 percent) of the 58 patients without atrial fibrillation had documented episodes of spontaneous paroxysmal supraventricular tachycardia (NS). During electrophysiologic study, 23 (77 percent) of the 30 patients with documented atrial fibrillation and 28 (48 percent) of the 58 patients without atrial fibrillation had inducible A-V reentrant tachycardia (Fig. 1). The patients with documented atrial fibrillation were significantly more likely to have inducible A-V reentrant tachycardia than were the patients without atrial fibrillation ($p < 0.025$).

TABLE II

Comparisons of Patients With and Without Spontaneous Paroxysmal Atrial Fibrillation

	Patients With Atrial Fibrillation (30 patients)	Patients Without Atrial Fibrillation (58 patients)	p Value
Spontaneous PSVT	9 (30%)	24 (41%)	NS
Inducible PSVT	23 (77%)	28 (48%)	<0.025
Organic heart disease	13 (43%)	15 (26%)	NS
Organic heart disease in 37 patients without inducible PSVT	6 of 7 (86%)	6 of 30 (20%)	<0.005
Organic heart disease or inducible PSVT, or both	29 (97%)	34 (59%)	<0.0005

PSVT = atrioventricular reentrant paroxysmal tachycardia.

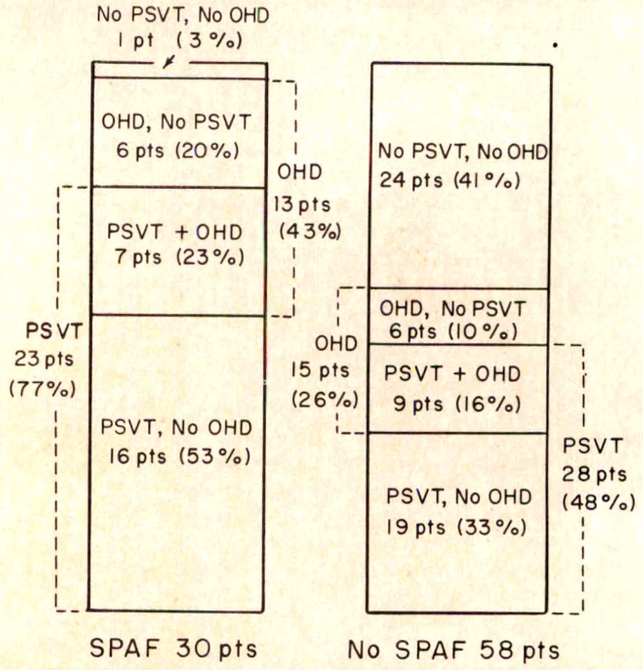

FIGURE 1. Association of spontaneous paroxysmal atrial fibrillation (SPAF) with inducible A-V reentrant tachycardia (PSVT) or organic heart disease (OHD), or both. The 30 patients (pts) with documented episodes of atrial fibrillation are shown on the **left**, and the 58 patients without such episodes are shown on the **right**. See text for discussion.

Thirteen (43 percent) of the 30 patients with documented atrial fibrillation and 15 (26 percent) of the 58 patients without atrial fibrillation had organic heart disease (Table I, Fig. 1). These prevalence levels were not significantly different. However, six (86 percent) of the seven patients with documented atrial fibrillation who did not have inducible A-V reentrant paroxysmal tachycardia had organic heart disease (Fig. 1). In contrast, only 6 (20 percent) of the 30 patients without atrial fibrillation who did not have inducible A-V reentrant tachycardia had organic heart disease ($p < 0.005$) (Fig. 1). Viewed in another way, 29 (97 percent) of the 30 patients with documented atrial fibrillation had inducible A-V reentrant tachycardia or organic heart disease, or both. In contrast, only 34 (59 percent) of the 58 patients without atrial fibrillation had inducible A-V reentrant tachycardia or organic heart disease, or both ($p < 0.0005$).

Inducible A-V reentrant tachycardia in patients with and without spontaneous paroxysmal atrial fibrillation: The finding that patients with documented atrial fibrillation were significantly more likely to have inducible A-V reentrant tachycardia than patients without atrial fibrillation suggested that there is an association between spontaneous paroxysmal atrial fibrillation and inducible A-V reentrant tachycardia. Of the 51 patients with inducible A-V reentrant tachycardia, 23 had documented atrial fibrillation whereas 28 did not. We further scrutinized the patients with inducible A-V reentrant tachycardia, to determine

whether the patients with documented atrial fibrillation differed from the patients without atrial fibrillation with respect to clinical and electrophysiological characteristics.

There were no apparent differences between these two groups of patients with inducible A-V reentrant tachycardia with respect to clinical characteristics. Ages ranged from 15 to 61 years (mean ± standard error of the mean, 34 ± 3) among patients with documented atrial fibrillation, and from 12 to 64 years (mean 35 ± 3) among patients without atrial fibrillation (NS). Nineteen (83 percent) of the 23 patients with documented atrial fibrillation and 17 (61 percent) of the 28 patients without atrial fibrillation were male (NS). Seven (30 percent) of the 23 patients with documented atrial fibrillation and 9 (32 percent) of the 28 patients without atrial fibrillation had organic heart disease (NS) (Fig. 1).

We next compared sinus nodal and atrial properties in these two groups of patients with inducible A-V reentrant tachycardia. Corrected sinus nodal recovery times ranged from 120 to 470 ms (mean 295 ± 19) in the 23 patients with documented atrial fibrillation and from 124 to 490 ms (mean 307 ± 21) in the 28 patients without atrial fibrillation (NS). Calculated sinoatrial conduction times ranged from 20 to 125 ms (mean 75 ± 6) in the patients with documented atrial fibrillation and from 25 to 142 ms (mean 90 ± 7) in the patients without atrial fibrillation (NS). Atrial functional refractory periods ranged from 200 to 330 ms (mean 261 ± 12) in the patients with documented atrial fibrillation and from 200 to 350 ms (mean 254 ± 6) in the patients without atrial fibrillation (NS). Atrial effective refractory periods ranged from 160 to 290 ms (mean 225 ± 8) in the patients with documented atrial fibrillation, and from 140 to 330 ms (mean 207 ± 7) in the patients without atrial fibrillation (NS). Dispersion of atrial effective refractory periods (between high right atrium and coronary sinus) ranged from 10 to 70 ms (mean 30 ± 10) in seven patients with documented atrial fibrillation and from 10 to 50 ms (mean 24 ± 7) in five patients without atrial fibrillation (NS).

We also examined characteristics of the induced tachycardias in these two groups of patients with inducible A-V reentrant tachycardia. Cycle lengths of induced A-V reentrant tachycardia ranged from 250 to 375 ms (mean 320 ± 8) in the patients with documented atrial fibrillation and from 260 to 440 ms (mean 319 ± 9) in the patients without atrial fibrillation (NS) (Fig. 2). The location of the anomalous pathway (the site of input to the atria during the orthodromic variety of A-V reentrant tachycardia) was the left ventricular free wall in 9 (39 percent), septal or paraseptal wall in 10 (43 percent) and the right free wall in 4 (17 percent) of the 23 patients with documented atrial fibrillation; the site was the left free wall in 13 (46 percent), septal or paraseptal wall in 5 (18 percent) and the right free wall in 10 (36 percent) of the 28 patients without atrial fibrillation (NS). One (4 percent) of the 23 patients with and 2 (7 percent) of the 28 patients without atrial fibrillation had a second anomalous pathway,[26] which could possibly

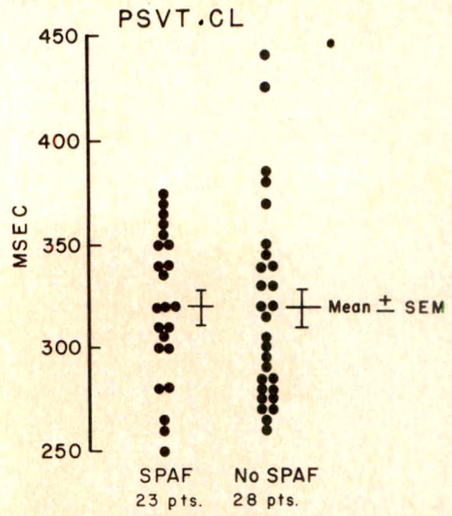

FIGURE 2. Cycle lengths (CL) of induced A-V reentrant tachycardia (PSVT). The cycle lengths did not differ in patients (**left**) with and without (**right**) documented spontaneous paroxysmal atrial fibrillation (SPAF).

allow two inputs to the atria during A-V reentrant tachycardia (NS). Induced tachycardias were different in these two groups of patients in one respect: Induced A-V reentrant tachycardia was observed to degenerate spontaneously to atrial fibrillation in 6 (26 percent) of the 23 patients with documented episodes of spontaneous paroxysmal atrial fibrillation (Fig. 3) but in none of the 28 patients without such episodes ($p < 0.025$).

In summary, the only significant difference between the patients with inducible A-V reentrant tachycardia who did and did not have documented episodes of spontaneous paroxysmal atrial fibrillation was that spontaneous degeneration of induced A-V reentrant tachycardia to atrial fibrillation was observed exclusively in the former group.

Organic heart disease in patients without inducible A-V reentrant tachycardia: We also studied the 37 patients without inducible A-V reentrant tachycardia in an attempt to determine how the 7 patients with documented atrial fibrillation differed from the 30 patients without atrial fibrillation. We found that organic heart disease was more commonly present among the patients with than among those without atrial fibrillation (see earlier) (Fig. 1).

Six (86 percent) of the seven patients with documented atrial fibrillation had organic heart disease. Four of these patients had heart disease that was hemodynamically significant: Three had congestive cardiomyopathy and one had calcific mitral stenosis (calculated mitral valve area 1.3 cm^2). Of the remaining two patients with heart disease, one had clinical, echocardiographic and angiographic evidence of mitral valve prolapse, and one had the echocardiographic finding of asymmetric septal hypertrophy (interventricular septum to left ventricular posterior wall thickness ratio of 1.8) but no resting or provokable left ventricular outflow tract obstruction. Therefore, among these seven pa-

tients without inducible A-V reentrant tachycardia, the occurrence of spontaneous paroxysmal atrial fibrillation probably was related to organic heart disease in four (atrial stretch), and possibly in two other patients.

Six (20 percent) of the 30 patients without documented atrial fibrillation had organic heart disease. Three of these patients had heart disease that was hemodynamically significant: One had congestive cardiomyopathy, one had a previous myocardial infarction and congestive failure, and one had hypertensive heart disease with cardiomegaly. Of the remaining three patients with heart disease, one had angina pectoris, one had mild hypertensive heart disease and one had an ostium secundum atrial septal defect (with a pulmonary to systemic blood flow ratio of 2.0).

Discussion

Some patients with preexcitation have recurrent paroxysmal supraventricular tachycardia or paroxysmal atrial fibrillation or both.[1–4] The former usually reflects the occurrence of A-V reentrance, in which an impulse conducts from the atria in anterograde manner over the normal pathway (A-V node and His-Purkinje system) to the ventricles, and then in retrograde manner over the anomalous pathway (Kent bundle) to the atria.[5–8] Induction of this variety of paroxysmal tachycardia requires the presence of specific measurable cardiac electrophysiologic properties, namely, the ability of the normal pathway to conduct sequential impulses in an anterograde direction and the ability of the anomalous pathway to conduct sequential impulses in a retrograde direction.[8] In contrast, the pathophysiology of paroxysmal atrial fibrillation in patients with preexcitation is less clear.

Several groups of investigators have suggested that, in some patients with preexcitation, initiation of paroxysmal atrial fibrillation could relate to the occurrence of A-V reentrant tachycardia.[9–11] While performing

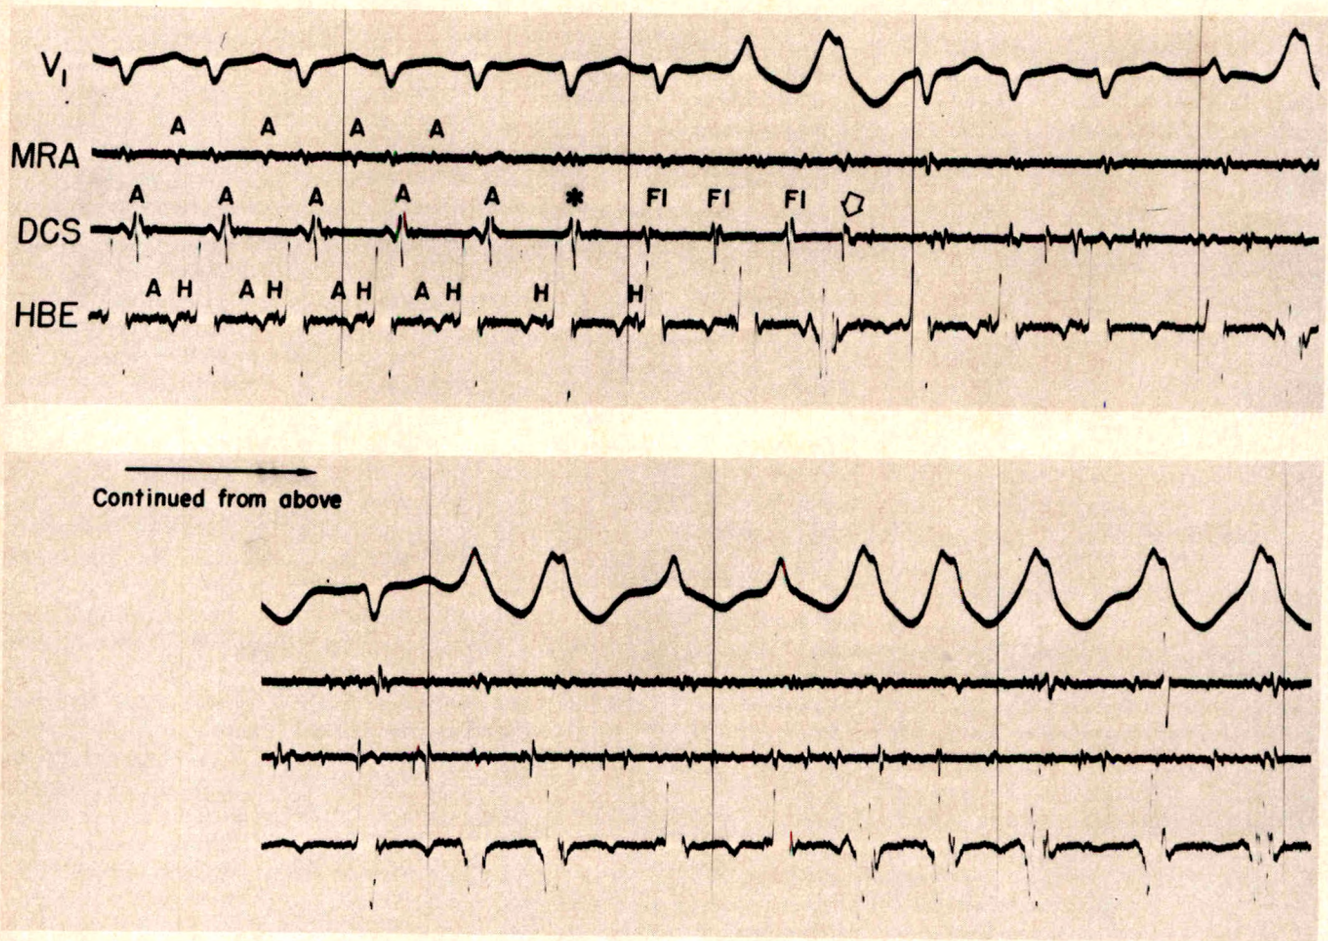

FIGURE 3. Continuous recording showing spontaneous degeneration of induced A-V reentrant tachycardia to atrial fibrillation. Shown are electrocardiographic lead V_1 and mid right atrial (MRA), distal coronary sinus (DCS), and His bundle (HBE) electrograms. Time lines are at 1 s intervals. The first several beats (**top panel, left**) reflect A-V reentrant tachycardia (notice that coronary sinus electrogramsprecede right atrial electrograms). The sixth coronary sinus deflection (**asterisk**) is premature, and is followed by several beats of atrial flutter (FI). The **arrow** marks the approximate onset of atrial fibrillation (notice the subsequent fragmentation and irregularity of atrial electrograms). After the onset of atrial fibrillation, several beats are normally conducted before the typical features of atrial fibrillation with anterograde conduction over an anomalous pathway are established (**lower panel**).

cardiac electrophysiologic studies in patients with preexcitation, these investigators observed degeneration of induced A-V reentrant tachycardia to atrial fibrillation. Campbell et al.[10] reported on 10 patients whose atrial fibrillation resulted from spontaneous (not related to cardiac pacing) degeneration of induced A-V reentrant tachycardia, and an additional 6 patients in whom atrial fibrillation resulted from atrial or ventricular stimulation during induced tachycardia or from ventricular pacing alone. The spontaneous degenerations appeared to relate to the occurrence of either premature atrial beats or intraatrial conduction delay during induced A-V reentrant tachycardia. Sung et al.[11] reported on seven patients in whom spontaneous degeneration of induced tachycardia appeared to relate to the occurrence of premature atrial beats. Both Sung and Campbell and their co-workers took care to exclude from their reports patients in whom degeneration occurred during catheter manipulation. However, neither report clearly established the relevance of these laboratory observations to the occurrence of spontaneous paroxysmal atrial fibrillation. Only 6 of the 16 patients reported on by Campbell et al. and 5 of the 7 patients reported on by Sung et al. had documented episodes of atrial fibrillation before the electrophysiologic study was performed.

Association between presence of spontaneous fibrillation and inducible A-V reentrant tachycardia: In the present study, we studied a series of 88 patients with preexcitation in an attempt to determine how the 30 patients who had had electrocardiographically documented episodes of spontaneous paroxysmal atrial fibrillation differed from the 58 patients without documented atrial fibrillation. The patients with documented atrial fibrillation were significantly more likely to have inducible A-V reentrant tachycardia than were the patients without documented atrial fibrillation. In other words, there was a significant association between the presence of documented atrial fibrillation (a clinical event) and the presence of inducible A-V reentrant tachycardia (a laboratory event). The significance of this association merits further discussion.

In a previous study of patients with preexcitation, we[4] noted that the presence or absence of inducible A-V reentrant tachycardia correlated strongly with the clinical occurrence of paroxysmal supraventricular tachycardia. For example, we found that the large majority of patients with inducible A-V reentrant tachycardia had had documented episodes of paroxysmal supraventricular tachycardia or paroxysmal palpitation without documented arrhythmia (suspected A-V reentrant tachycardia). In the present study, we noted that, although 77 percent of our patients with documented atrial fibrillation had inducible A-V reentrant tachycardia, only 30 percent of these patients had had documented episodes of paroxysmal supraventricular tachycardia. It is likely that many of our patients with preexcitation and documented atrial fibrillation had episodes of A-V reentrant tachycardia that degenerated to atrial fibrillation; (therefore it was atrial fibrillation rather than A-V reentrant tachycardia that was documented electrocardiographically). This hypothesis is supported by recent observations in two of our patients with preexcitation (one reported on).[27] These two patients, referred to us because of recurrent episodes of paroxysmal atrial fibrillation, had not had documented episodes of paroxysmal supraventricular tachycardia but were found to have inducible A-V reentrant tachycardia. After electrophysiologic studies, these patients were issued transmitters, enabling them to report by telephone future cardiac rhythms disturbances. Their rhythm during the first minutes of subsequent episodes of paroxysmal palpitation was paroxysmal supraventricular tachycardia (telephone transmissions), but later during these episodes (on arrival in emergency room) the rhythm was atrial fibrillation.

Differences between patients with A-V reentrant tachycardia with and without atrial fibrillation: If one accepts the hypothesis that spontaneous paroxysmal atrial fibrillation is sometimes (or frequently) the result of paroxysmal A-V reentrant tachycardia, then it is germane to ask why some patients with preexcitation and A-V reentrant tachycardia have atrial fibrillation and others do not. We attempted to answer this question by further studying our patients who had inducible A-V reentrant tachycardia and comparing the patients with and without documented atrial fibrillation. These two groups of patients did not differ with respect to clinical attributes (age, sex or the presence of organic heart disease) or atrial properties (including dispersion of effective refractory period between high right atrium and coronary sinus). Because Dreifus et al.[28] suggested that paroxysmal atrial fibrillation in patients with preexcitation may be associated with sinus nodal dysfunction, we also examined sinus nodal properties. However, our patients with and without documented atrial fibrillation did not differ with respect to corrected sinus nodal recovery time or calculated sinoatrial conduction time.

Wyndham[29] and Sung[11] and their co-workers reported that atrial vulnerability in human beings increases as atrial cycle length decreases. We therefore hypothesized that in patients with preexcitation who have spontaneous episodes of paroxysmal atrial fibrillation A-V reentrant tachycardia may be faster than in patients without such episodes. However, we found that our patients with and without documented atrial fibrillation had induced A-V reentrant tachycardias of almost identical cycle lengths. We also found that neither anomalous pathway location (the site of input to the atria during A-V reentrant tachycardia) nor the prevalence of two anomalous pathways (possibly allowing two inputs to the atria during A-V reentrant tachycardia) differed in patients with and without documented atrial fibrillation. These two groups of patients differed in only one respect: Spontaneous degeneration of induced A-V reentrant tachycardia to atrial fibrillation was observed significantly more often in the patients who had documented atrial fibrillation. In other words, the only distinguishing characteristic of the patients with inducible A-V reentrant tachycardia

who had documented atrial fibrillation was that they had (in the laboratory) the hypothesized event itself.

There are several possible explanations for why some patients with preexcitation and A-V reentrant tachycardia have paroxysmal atrial fibrillation and others do not. (1) There could be differences in dispersion of atrial refractoriness on a microscopic scale (rather than on a macroscopic scale, as measured in the present study).[25] (2) There could be differences in hemodynamic responses to A-V reentrant tachycardia (hemodynamic variables were not measured in the present study).[30,31] (3) There could be differences in autonomic responses (perhaps related to hemodynamic responses) to A-V reentrant tachycardia; for example, an increase in parasympathetic nervous tone during A-V reentrant tachycardia could predispose to the occurrence of paroxysmal atrial fibrillation.[32,33]

Role of organic heart disease: It is reasonable to assume that patients with preexcitation and significant underlying organic heart disease are predisposed to the occurrence of paroxysmal atrial fibrillation. However, it appears that only a minority of patients with preexcitation and paroxysmal atrial fibrillation have heart disease. Wellens[9] diagnosed heart disease in 9 of 27 patients, whereas Campbell et al.[10] found heart disease in 6 of 32 patients with paroxysmal atrial fibrillation. In the present study, we found organic heart disease (of several different varieties) in 13 (43 percent) of our patients with preexcitation and documented episodes of spontaneous paroxysmal atrial fibrillation. Similar to Campbell et al.[10] we did not find a greater prevalence of organic heart disease in patients with than in patients without paroxysmal atrial fibrillation.

If one accepts the hypothesis that patients with preexcitation who have A-V reentrant tachycardia are predisposed to the occurrence of paroxysmal atrial fibrillation, then it is reasonable to ask why some patients with preexcitation who do not have A-V reentrant tachycardia have paroxysmal atrial fibrillation. When we limited our analysis to patients who did not have inducible A-V reentrant tachycardia, we found that patients with documented atrial fibrillation had a much greater prevalence of organic heart disease than did patients without documented atrial fibrillation. In fact, six (83 percent) of the seven patients with documented atrial fibrillation who did not have inducible A-V reentrant tachycardia had organic heart disease. In four of these six patients, organic heart disease was clearly hemodynamically significant (three had congestive cardiomyopathy and one had significant mitral stenosis) and in all probability was related to the occurrence of paroxysmal atrial fibrillation. In the other two patients, organic heart disease was not hemodynamically significant and may or may not have been related to the occurrence of paroxysmal atrial fibrillation.

Therapeutic implications: The usual approach to long-term management (prophylaxis) of the patient with preexcitation and recurrent atrial fibrillation is to administer one or more drugs that increase the anterograde refractoriness of the anomalous pathway,[34–39] or to divide surgically the anomalous pathway[40] to prevent rapid ventricular rates during recurrences of atrial fibrillation. A different approach would be to administer drugs in an attempt to actually prevent recurrences of atrial fibrillation. However, this latter approach is poorly understood, and clinical trial and error is currently the only method available for evaluating drug responses. In contrast, there is far more understanding of pharmacologic prophylaxis of A-V reentrant tachycardia,[34–39,41–44] and serial drug testing can be performed in the catheterization laboratory,[43] eliminating the need for extensive clinical trial and error.

The demonstration in this study that patients with preexcitation and spontaneous paroxysmal atrial fibrillation usually have inducible A-V reentrant tachycardia implies that administration of drugs to these patients to prevent paroxysmal supraventricular tachycardia could also prevent recurrences of atrial fibrillation. It also implies that surgical division of the anomalous pathway (the retrograde limb of A-V reentrant tachycardia) could also prevent recurrences of atrial fibrillation.

Washington, D.C.

To assess the type and prevalence of cardiac abnormalities in heavy drinkers with and without overt congestive heart failure, M mode echocardiography was performed in 11 symptomatic chronic alcoholics with dilated (congestive) cardiomyopathy and in 22 asymptomatic chronic alcoholics. Echocardiographic data in both groups were adjusted for age and body surface area using previously derived regression equations. All 11 symptomatic patients had a significantly decreased left ventricular percent fractional shortening (mean 14 percent, normal range 28 to 44) along with significant increases in left ventricular systolic and diastolic dimensions (mean increases of 105 and 48 percent above normal, respectively), left atrial dimension (mean increase 21 percent) and estimated left ventricular mass (mean increase 105 percent). Among the 22 asymptomatic patients, 15 (68 percent) demonstrated significant increases in at least one of the following echocardiographic variables: left ventricular mass, left ventricular dimensions, septal and left ventricular wall thicknesses, and left atrial dimension.

Asymptomatic patients could be classified into two subgroups: (1) those with a left ventricular diastolic dimension less than 10 percent above the normal predicted value and an increased left ventricular wall thickness to radius ratio (mean increase 16 percent above normal) and upper normal percent fractional shortening, and (2) those with a left ventricular diastolic dimension 10 to 24 percent above normal and a slightly subnormal thickness to radius ratio and lower normal percent fractional shortening. Echocardiographic abnormalities in asymptomatic chronic alcoholics did not correlate with the presence or absence of auscultatory abnormalities on physical examination and appear to reflect an earlier stage in the spectrum of alcoholic disease before the development of dilated cardiomyopathy.

One of the complications of chronic alcoholism is the development of dilated (congestive) cardiomyopathy. Despite some controversy as to its etiologic role in cardiomyopathy, ethanol has been incriminated in the production of left ventricular failure by a direct cardiotoxic effect.[1–4] The hemodynamic features of the disease at this stage reflect depression of myocardial contractile function and include ventricular dilatation, decreased left ventricular ejection fraction and increased end-diastolic pressure in both ventricles. Left ventricular angiography has also demonstrated an increase in left ventricular wall thickness and overall myocardial mass.[5] Previous echocardiographic studies[6,7] of dilated cardiomyopathy have shown increased left ventricular diastolic and systolic dimensions, markedly decreased ventricular septal and posterior left ventricular wall motion, and a decrease in left ventricular percent fractional shortening and mean velocity of circumferential fiber shortening.

Evidence of cardiac malfunction has also been demonstrated in chronic alcoholics without clinical evidence of heart disease both invasively[8,9] and by noninvasive measurement of systolic time inter-

ARD = aortic root dimension; Aus = auscultation; BP = blood pressure; BSA = body surface area; FC = New York Heart Association functional class; LAD = left atrial dimension; LV = left ventricular; LVIDd = left ventricular internal dimension in diastole; LVIDs = left ventricular internal dimension in systole; LVWT = left ventricular diastolic wall thickness; % FS = percent fractional shortening; t = average left ventricular diastolic thickness, or (LVWT + VST)/2; t/r = thickness to radius ratio, or the ratio of average left ventricular diastolic thickness to half the ventricular internal diastolic dimension; VST = ventricular septal thickness; ? = uncertain.

vals.[10–13] Although one recent study[13] demonstrated increased ventricular septal and left ventricular wall thickness on echocardiography in approximately 45 percent of a group of chronic alcoholic subjects, another[14] documented no difference from normal controls in variables of cardiac structure and function. However, the patients in the latter study had undergone a prolonged period of abstinence from alcohol (mean 3.1 years, range 3 months to 16 years). Clinical improvement of left ventricular failure was previously reported in patients after complete cessation of alcohol consumption.[3,8,15]

To further investigate possible changes in cardiac structure and function induced by chronic excessive intake of alcohol, we studied chronic alcoholic subjects with and without cardiac symptoms by M mode echocardiography and compared the findings in these two groups with echocardiographic data obtained from normal subjects.[16,17]

Methods

Study Patients

Patients admitted to the Veterans Administration Hospital, Washington, D.C., with a history of chronic alcoholism were evaluated. Patients were classified into two groups: those with and those without overt evidence of heart disease.

Patients without symptoms of cardiac disease: Twenty-two chronic alcoholic patients admitted to the Alcohol Rehabilitation Service at the Veterans Hospital over a 3 month period were evaluated by physical examination, electrocardiography, chest roentgenography and echocardiography. This group of 21 men and 1 woman (age range 31 to 57 years, mean 46) had no symptoms of heart disease and no history compatible with angina pectoris, previous myocardial infarction, valvular heart disease or hypertension. All patients had been heavy drinkers, that is, consuming an average quantity equivalent to at least 12 ounces of whiskey daily for at least 6 years (the majority for greater than 15 years). All patients had abstained from drinking while on the ward for at least 2 weeks before echocardiographic evaluation.

Patients with clinical evidence of cardiomyopathy: Eleven chronic alcoholic patients (aged 28 to 66 years) with cardiac catheterization-proved dilated (congestive) cardiomyopathy[5] also were studied. None had a history compatible with congenital, rheumatic, hypertensive or atherosclerotic heart disease. All patients had a history of chronic alcoholism for more than 10 years, and all had had symptoms of congestive heart failure for 1 to 6 years. At the time of echocardiographic study, three were in New York Heart Association[18] functional class IV, three were in class III, and five in class II (Table I). All had had initial improvement with therapy. The five patients in class II had been more symptomatic at the time of catheterization, but their condition had improved with treatment. Only patients whose clinical status warranted evaluation by cardiac catheterization were included in the symptomatic group.

Normal subjects: Echocardiographic data from patients in both the symptomatic and asymptomatic groups of chronic alcoholics were adjusted for age and body surface area using regression equations derived from 136 normal subjects, which were previously reported from our laboratory.[16,17] No normal subject had a history of heart disease or hypertension and all had normal findings on physical examination, electrocardiography and chest roentgenography. In addition, none had echocardiographic evidence of pericardial effusion or valvular heart disease.

Echocardiography

Echocardiograms were recorded using an Ekoline 20A ultrasound unit, Honeywell 1856 line scan recorder, Hewlett-Packard X-Y display and a custom-built video amplifier.[19] Measurements were made according to the recommendations of the American Society of Echocardiography.[20] Aortic root and left atrial dimensions were recorded by angling the ultrasonic beam from the mitral valve into the aortic root.[21] At this point, minor adjustments of transducer orientation were made until the beam was reflected from the aortic valve leaflets. Measurement of aortic root dimension was made at end-diastole at the onset of the QRS complex; the left atrium was measured at the maximal dimension at end-systole.[20] The posterior wall of the left atrium was identified utilizing a custom-built switched gain circuit.[22]

Ventricular measurements: The internal dimension of the left ventricle at end-diastole was measured at the onset of the QRS complex; the end-systolic dimension was measured at the nadir of septal motion (that is, when the ventricular

Tach = tachycardia; other abbreviations as in Table I.

septum was farthest from the anterior chest wall). Both measurements were made with the ultrasonic beam passing through the left ventricle slightly caudal to the tip of the mitral valve using the T scan technique.[19] The diastolic thickness of the ventricular septum and the left ventricular posterior wall were measured in the same portion of the record used to measure left ventricular internal dimension.[20] Measurements were made at the onset of the QRS complex using the leading edge method and the switch gain circuit to help identify the left ventricular epicardial surface.[20,22]

Percent fractional shortening of the left ventricle was calculated by the formula[23]: (LVIDd − LVIDs)/LVIDd, where LVIDd is end-diastolic dimension and LVIDs is end-systolic dimension.

Left ventricular (LV) mass was estimated as previously described[21,24,25]: LV mass = [1.05] [(LVIDd + IVS + LVPW)^3 − (LVIDd)^3], where IVS denotes the diastolic thickness of the ventricular septum and LVPW represents left ventricular posterior wall thickness.

A diastolic thickness to radius (t/r) ratio for the left ventricle was calculated by the formula:

$$t/r = LVWTa/1/2\ LVIDd,$$

where LVWTa thickness was defined as the average of the diastolic ventricular septal and left ventricular posterior wall thicknesses.

Data analysis: Echocardiographic data for the symptomatic and asymptomatic alcoholic groups are recorded in Tables I and II. These data also were expressed as a percent of the predicted normal value for each variable using age and body surface area, as previously described[16,17] (Fig. 1 to 4). Body surface area was estimated from the height and weight by the Boothby and Sandiford modification[26] of the formula of DuBois and DuBois.[27] The percent predicted data are plotted on graphs for each variable, displaying the 95 percent prediction interval for normal subjects as a percent of the mean (Fig. 1 to 4). The advantage of expressing *each* echocardiographic data point as a percent of the predicted normal value is that it allows the data from each subject to be compared with the normal values and thereby avoids errors in data analysis that might arise from merely adjusting a single group mean echocardiographic value for the mean age and body surface area.

Statistical comparisons of the data in the asymptomatic and symptomatic chronic alcoholic groups with the predicted normal data were performed utilizing F tests and Student's *t* test with appropriate corrections.[28]

Results

Clinical and Hemodynamic Data

Symptomatic chronic alcoholic patients: In every patient, physical examination revealed cardiomegaly with signs of left or biventricular failure in the absence of hypertension. Third and fourth heart sounds and a murmur of mitral regurgitation were the most common abnormal auscultatory findings. Chest roentgenograms revealed generalized cardiomegaly in all with signs of pulmonary venous hypertension in the more severely symptomatic patients. The electrocardiograms all showed left ventricular hypertrophy or interventricular conduction delay, or both. One patient had left bundle branch block, one was in atrial fibrillation at the time of study, and three others had recently had conversion to sinus rhythm from atrial fibrillation. At cardiac catheterization, all patients had left ventricular dilatation with symmetric but hypokinetic wall motion and increased left ventricular end-diastolic pressure; six had evidence of mild and two had evidence of moderate mitral regurgitation. Coronary angiograms were entirely normal in all but four patients. These four patients had only minimal (25 to 50 percent) narrowing of the luminal diameter of one or two vessels, which was not considered hemodynamically significant.

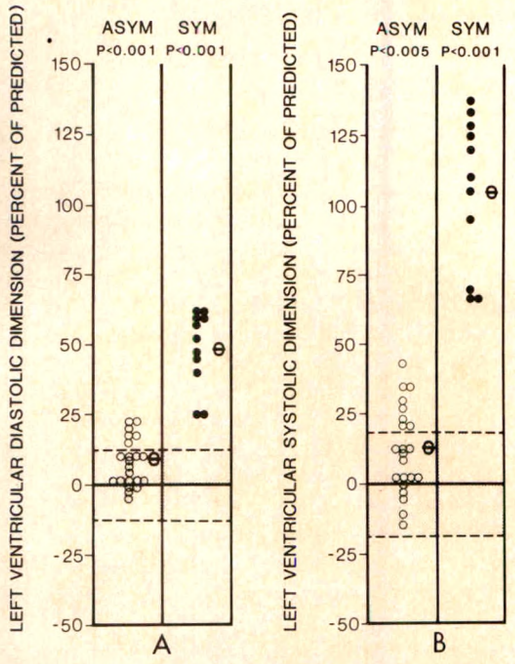

FIGURE 1. Plot of the percent differences between observed and predicted normal values for left ventricular internal dimension in diastole (**A**) and systole (**B**) for 22 asymptomatic (ASYM) (**open circles**) and 11 symptomatic (SYM) (**closed circles**) subjects. The **shaded areas** represent the 95 percent prediction intervals for normal subjects obtained for each echocardiographic variable. Mean percent differences (**open circles with horizontal bar**) are depicted to the right of each group of data points. P = probability.

FIGURE 2. All values are expressed as a percent above or below the predicted value calculated for each patient based on size and body surface area. A value of 0 percent means that the actual value corresponds to the predicted value. SD = standard deviation; SEM = standard error of the mean; other abbreviations as in Table I.

Asymptomatic chronic alcoholics: The 22 chronic alcoholics in this group had no symptoms of cardiac decompensation or systemic hypertension. Cardiac examination revealed mild abnormalities in 16 (72 percent) of these patients (Table II): A fourth heart sound was present in 13 patients, a third heart sound in 4 (18 percent), an increased pulmonary component of the second heart sound (P_2) in 1 (4 percent) and tachycardia in 1. Chest roentgenograms in this group revealed no cardiomegaly or evidence of pulmonary venous hypertension. Electrocardiograms were normal or nonspecific, demonstrating sinus tachycardia in one patient (4 percent), left axis deviation in two patients (8 percent) and nonspecific ST-T wave abnormalities in four patients (18 percent).

Echocardiographic Data

Left ventricular internal dimension (Fig. 1, Tables I to III): Left ventricular internal dimension at end-diastole and at end-systole was increased in all 11 symptomatic patients. Mean left ventricular end-diastolic dimension was increased 48 percent above the mean normal value ($p < 0.001$), whereas mean left ventricular end-systolic dimension was increased 105 percent above the normal mean ($p < 0.001$). Among the 22 asymptomatic chronic alcoholics, left ventricular diastolic dimension was above the 95 percent normal prediction interval in 6 (27 percent), and systolic dimension was outside the 95 percent normal prediction interval in 8 patients (36 percent). Mean left ventricular diastolic dimension was 8 percent above the normal mean, whereas mean systolic dimension was 12 percent above the normal mean; both of these differences were statistically significant ($p < 0.001$ and < 0.005, respectively).

Ventricular septal and left ventricular posterior wall thickness (Fig. 2, Tables I to III): All patients in both the symptomatic and asymptomatic groups had a ventricular septal to left ventricular posterior wall thickness ratio of less than 1.3 to 1. Ventricular septal thickness was above the 95 percent normal prediction interval in 2 of the 11 symptomatic patients. In two other symptomatic patients, values were below the mean by a similar percent. Mean ventricular septal thickness was 2.4 percent above the normal mean, but this difference was not statistically significant. In contrast, among the 22 asymptomatic patients, 4 (18 percent) had values above and none had values below the normal 95 percent prediction interval. On average, mean ventricular septal thickness was 10 percent above the normal, a statistically significant difference ($p < 0.001$).

Left ventricular posterior wall thickness in diastole was above the normal prediction interval in 3 (27 percent) of the 11 symptomatic patients and below normal in none. Only one of these three patients (Case 3) had a ventricular septal thickness also above the normal prediction interval. Mean left ventricular wall thickness in the symptomatic group was 6 percent above normal (not a significant difference). In the asymptomatic group, 6 (27 percent) of 22 patients had left ventricular posterior wall thickness above the normal range and, again, none had values below this range. The 11 percent mean increase of left ventricular wall thickness above the normal mean was statistically significant ($p < 0.001$).

Aortic root and left atrial dimensions (Fig. 3, Tables I and II): Aortic root dimension was outside the prediction interval in only one symptomatic patient. Mean aortic root dimension in this group was not statistically different from normal (1.6 percent above normal mean). All 22 asymptomatic patients had a value for aortic root dimension falling within the 95 percent

prediction interval. In this asymptomatic group, the mean aortic root dimension (5 percent above normal mean) was not significantly different from normal.

Left atrial dimension was above the normal interval in 6 (60 percent) of 10 symptomatic patients (mean value 21 percent above the normal mean; $p < 0.01$). The presence of a significantly increased left atrial dimension was not positively correlated with the presence or absence of increased ventricular septal thickness or left ventricular wall thickness in the symptomatic group. (All symptomatic patients had increased left ventricular systolic and diastolic internal dimensions.) Only three (14 percent) of the asymptomatic patients had an increased left atrial dimension. Nonetheless, the mean increase in this group (7 percent) was significantly different from the normal mean ($p < 0.02$).

Left ventricular percent fractional shortening (Fig. 4A, 5A, Tables I and II): All 11 symptomatic patients had left ventricular systolic dysfunction as manifested by a left ventricular percent fractional shortening significantly ($p < 0.001$) below the normal range of 28 to 44 percent. Mean left ventricular percent fractional shortening in the symptomatic group was only 14 percent. Among the asymptomatic patients, one had a percent fractional shortening above the normal interval, and two had a value below this interval. The mean left ventricular percent fractional shortening in this group was 35 percent, a value not statistically different from the normal mean of 36 percent. Thus, on average, the asymptomatic group did not exhibit abnormal left ventricular systolic function.

When the data for left ventricular percent fractional shortening were plotted against the left ventricular internal dimension in diastole, an interesting trend became apparent. When the asymptomatic patients were classified into those with a left ventricular diastolic dimension less than 10 percent above the normal predicted value and those with a diastolic dimension 10 to 24 percent above the predicted value, the mean left ventricular percent fractional shortening in the two groups was 38 and 32 percent, respectively. This difference was significant ($p < 0.01$) (Fig. 5A). The symptomatic patients, all of whom had a left ventricular internal dimension greater than 25 percent above the normal mean predicted value, had a mean left ventricular percent fractional shortening of 14 percent. Although the symptomatic patients with a dilated left ventricle obviously had a lower percent fractional shortening, there was also a trend toward a smaller (albeit within normal range) fractional shortening percent in the asymptomatic patients with a larger (10 to 24 percent above predicted value) left ventricular diastolic dimension.

Left ventricular mass (Fig. 4B, Tables I and II): All but 1 of the 11 symptomatic patients had an estimated left ventricular mass above the normal interval. The mean left ventricular mass in this group (493 g) was 110 percent above the normal mean, a significant difference ($p < 0.001$). In addition, 9 of the 22 asymptomatic patients had an estimated left ventricular mass

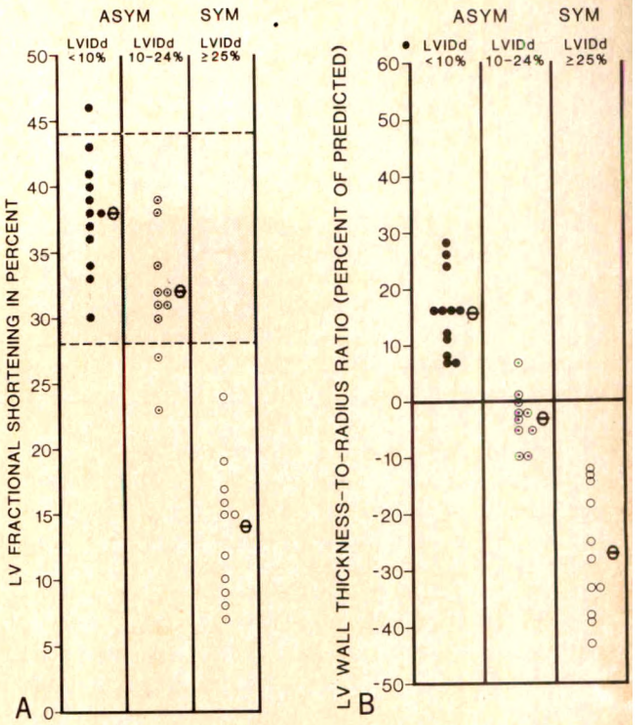

FIGURE 5. A, left ventricular percent fractional shortening is plotted for two asymptomatic subgroups, one with left ventricular diastolic dimension (LVIDd) less than 10 percent above the normal predicted, the second with LVIDd 10 to 24 percent above normal; and for symptomatic patients, all of whom had a diastolic dimension 25 percent or greater above normal. The **shaded area** represents the 95 percent normal prediction interval for percent fractional shortening. **B,** percent differences between observed and predicted normal values for left ventricular (LV) wall thickness to radius ratio are plotted for the two asymptomatic groups and the symptomatic patients. Abbreviations and format as in Figure 1.

above the normal range. The mean left ventricular mass in the asymptomatic group (302 g) was 33 percent above the estimated normal mean; this difference was also significant ($p < 0.001$).

Left ventricular thickness to radius ratio (Fig. 5B, Tables I to III): All 11 symptomatic patients demonstrated a subnormal diastolic thickness to radius ratio of the left ventricle, the mean being 27 percent below the normal predicted mean value. The asymptomatic group, on the other hand, had a mean thickness to radius ratio 7 percent above the normal value. Moreover, when the asymptomatic patients were classified into two subgroups based on left ventricular diastolic dimensions, that is, one group with a diastolic dimension less than 10 percent and another group with a diastolic dimension of 10 to 24 percent, the mean values for thickness to radius ratio of the left ventricle expressed as a percent of predicted were +16 and −3 percent, respectively. Of further interest, patients in the symptomatic group, all of whom had a left ventricular diastolic dimension greater than 25 percent above the predicted normal, had a thickness to radius ratio below the range

found in the asymptomatic patients. The differences among the three subgroups in the mean left ventricular wall thickness to radius ratios expressed as a percent of the predicted value were statistically significant ($p < 0.01$).

Clinical and Echocardiographic Comparison

Symptomatic chronic alcoholics: As expected, the echocardiographic findings of increased left ventricular and left atrial dimensions, increased left ventricular mass and decreased left ventricular percent fractional shortening correlated well with the physical findings of cardiomegaly and left or biventricular failure (third and fourth heart sounds) with or without mitral regurgitation.

Asymptomatic chronic alcoholics: Although 16 patients had abnormal physical findings, a fourth heart sound was the only abnormal finding in 10 patients. Eleven of these 16 patients had at least one abnormal echocardiographic finding among the following: left ventricular systolic or diastolic dimension, ventricular septal thickness or left ventricular wall thickness, left atrial dimension and estimated left ventricular mass. Both the patient with tachycardia and the patient with an increased intensity of the pulmonary component of the second heart sound had abnormal echocardiographic findings. Of the four patients with a third heart sound, two (50 percent) had significant echocardiographic abnormalities. However, four (67 percent) of the six patients without any abnormal physical findings also had one or more abnormal echocardiographic findings. Consequently, the presence or absence of significant echocardiographic abnormalities did not correlate well with the presence or absence of a third or fourth heart sound. Similarly, auscultatory findings could not predict whether an asymptomatic patient would fall into the subgroup with left ventricular diastolic dimension less than 10 percent or 10 to 24 percent above the predicted value.

Discussion

Alcoholic cardiomyopathy: Previous echocardiographic studies[6,7] in chronic alcoholics who have symptomatic heart disease have demonstrated increased left ventricular diastolic and systolic dimensions, markedly decreased ventricular septal and posterior left ventricular wall excursion and decreased left ventricular percent fractional shortening. In some patients, mild concentric left ventricular thickening on angiography has been reported.[5] In the present study, all 11 of the chronic alcoholic patients with physical findings of biventricular failure and catheterization-proved dilated (congestive) cardiomyopathy had echocardiographic evidence of increased left ventricular and left atrial dimensions, increased left ventricular mass and decreased left ventricular percent fractional shortening. All but one of these patients had a significant increase in estimated left ventricular mass. Although three of these patients had increased left ventricular posterior wall thickness and two had increased ventricular septal thickness, two others had *decreased* ventricular septal thickness. None of these abnormalities in septal or ventricular wall thickness were statistically significant.

Role of mitral regurgitation: Eight of our 11 symptomatic patients had mild to moderate mitral regurgitation. Although it is impossible to determine precisely the relative contributions of myocardial dysfunction versus mitral regurgitation in producing the increases in chamber dimensions and left ventricular mass and the decrease in left ventricular percent fractional shortening, several points are clear. First, the presence of mitral regurgitation was not necessary for the left ventricular dilatation and decompensation seen in these chronic alcoholic patients: Three of our 11 patients did not have mitral regurgitation. Second, the mitral regurgitation in our symptomatic patients had no obvious cause other than alcoholic heart disease; presumably, mitral regurgitation was caused by the abnormal mitral leaflet coaptation resulting from left ventricular dilatation. Finally, the left ventricle in our symptomatic alcoholics with mitral regurgitation differed markedly from that in 10 patients whom we have studied with mitral regurgitation on the basis of either rheumatic heart disease, ruptured chordae tendineae or mitral valve prolapse. Although the left ventricular diastolic dimensions were comparable in the two groups of patients, left ventricular percent fractional shortening was either normal or increased in our 10 patients with primary mitral regurgitation but was markedly decreased in our symptomatic chronic alcoholic patients (unpublished observations). Similar observations in patients with mitral regurgitation have previously been reported.[29]

Ventricular dysfunction in asymptomatic alcoholic patients: Although the changes in cardiac structure and function that occur after the development of the clinical findings of dilated cardiomyopathy have been well established, the cardiac findings in chronic alcoholics during the asymptomatic period have been less completely defined. Regan et al.[8] demonstrated that the left ventricle in chronic alcoholics without cardiac symptoms responds abnormally (with decreased left ventricular contractility and an abnormal increase in end-diastolic pressure) to increments in afterload compared with findings in nonalcoholic control subjects. Spodick and Zambrano and co-workers[10,11] and Wu et al.[12] studied chronic alcoholics who had no cardiac symptoms, and both groups found abnormal systolic time intervals indicative of left ventricular dysfunction. The alcoholics studied by Spodick et al were examined 2 to 3 days after their last ingestion of alcohol whereas those investigated by Wu et al. had abstained for a mean of 12 days (range 4 to 60). Reeves et al.[14] studied chronic alcoholics without overt heart disease by M mode echocardiography and documented no difference from normal control subjects in various structural and functional variables. However, the patients in their study had undergone a prolonged period of abstinence from alcohol (mean 3.1 years; range 3 months to 17 years).

The 22 asymptomatic patients in our study, who were studied after only 2 weeks to 3 months of abstinence from alcohol, are more similar in clinical status to the patients of Spodick,[10] Zambrano,[11] Wu,[12] and Askanas[13] and their co-workers than to those studied by Reeves et al.[14] Fifteen (68 percent) of our 22 patients had at least one significant abnormality on echocardiography after the data were adjusted for age and body surface area. The most frequent abnormality (not considering thickness to radius ratio) was an increase in estimated left ventricular mass, observed in nine patients. Seven patients had increased left ventricular internal dimension (systolic or diastolic, or both), six had increased wall thickness (septal or left ventricular posterior, or both), one had both increased left ventricular dimensions and wall thickness and three had increased left atrial dimension.

The asymptomatic as well as the symptomatic patients exhibited significant mean increases in left ventricular internal dimensions, left atrial dimension and estimated left ventricular mass compared with normal subjects, but these increases, not unexpectedly, were much greater in the symptomatic group. The asymptomatic patients differed from the symptomatic patients in demonstrating a significant, albeit small (10 to 11 percent), increase in mean (septal and left ventricular posterior) wall thickness while maintaining a normal mean left ventricular percent fractional shortening. Although these echocardiographic findings are similar to those of Askanas et al.,[13] the mean increases in ventricular septal and left ventricular wall thickness (22 and 19 percent, respectively) they reported in their chronic alcoholic patients were somewhat greater than in our group.

Additional insight into the asymptomatic chronic alcoholics was obtained by classifying these patients into two subgroups on the basis of left ventricular diastolic dimension. One group, with a left ventricular diastolic dimension less than 10 percent above the normal predicted value, had an average wall thickness increased out of proportion to the increased left ventricular diastolic dimension (mean thickness to radius ratio +16 percent above normal predicted), and a mean left ventricular percent fractional shortening of 38 percent that, although normal, was slightly above the normal mean of 36 percent. The second group, with left ventricular diastolic dimensions ranging from 10 to 24 percent above the normal, had a mean left ventricular wall thickness to radius ratio (mean −3 percent) slightly below normal and a mean left ventricular percent fractional shortening of 32 percent that, although normal, was below the normal mean. The symptomatic patients, all of whom had a left ventricular diastolic dimension greater than 25 percent above the normal predicted value, had a significantly decreased left ventricular thickness to radius ratio (mean −27 percent below predicted) and left ventricular percent fractional shortening (mean 14 percent). Clinically, the presence and type of echocardiographic abnormalities in both subgroups of asymptomatic patients were not reliably predicted by the presence on auscultation of a third or fourth heart sound.

Models of preclinical stages of alcoholic heart disease: Our data are generally in agreement with the work of Ford[30] and Grossman et al.,[31] who suggested that, in the compensated left ventricle, the myocardial fibers undergo hypertrophy, that is, left ventricular wall thickness increases, with increases in left ventricular dimension (volume) in order to normalize wall stress. In this regard, our echocardiographic data in the asymptomatic subjects are compatible with two models that might explain the response of the left ventricle to a toxic substance such as alcohol. The first model postulates that every asymptomatic subject goes through an initial stage in which there is mild left ventricular dilatation with an increase in left ventricular wall thickness that is proportionately greater than the increase in internal dimension, resulting in an increased thickness to radius ratio. At this point, left ventricular function is normal. Subsequently, with continued consumption of alcohol, left ventricular dilatation progresses, but wall thickening does not keep pace, yielding a thickness to radius ratio which is slightly decreased. Left ventricular wall stress at this stage is presumably normal or nearly normal, and systolic function is beginning to be impaired. Finally, with ventricular decompensation, left ventricular dilatation is markedly increased but the left ventricular thickness to radius ratio is decreased, which results in a significant increase in left ventricular wall stress. A second model postulates that there are two distinct subgroups of asymptomatic subjects whose hearts respond differently to the damage produced by alcohol. One group exhibits mild left ventricular dilatation with a proportionately greater increase in wall thickness associated with an increased thickness to radius ratio, normal or reduced wall stress and normal or increased percent fractional shortening. Patients who respond this way may have a stable clinical course and be relatively resistant to the toxic effects of alcohol on the heart. A second group, destined to have left ventricular decompensation (dilatation and decreased percent fractional shortening) with continued alcohol intake, responds to chronic consumption of alcohol with a moderately increased left ventricular internal dimension and a proportionately smaller increase in wall thickness. The resultant left ventricular thickness to radius ratio is normal or slightly decreased, and the percent fractional shortening is in the lower range of normal. Patients in this second group may be destined, with continued consumption of alcohol, to progress to the end stage cardiomyopathy characteristic of our symptomatic patients.

Implications: These models of the clinical spectrum of alcoholic heart disease are, of course, only speculative. Long-term prospective studies of a large number of chronic alcoholic subjects are required before it can be determined whether one of these models accurately explains the clinical progression of patients from an early stage of mild left ventricular dilatation and wall thickening with normal systolic function to the end

stage of overt, clinically apparent decompensation. If prospective studies confirm these speculations, echocardiography should prove very useful clinically as a method for identifying specific patients at high risk of developing cardiomyopathy. Special efforts could then be made to convince these high risk patients to stop their consumption of alcohol.

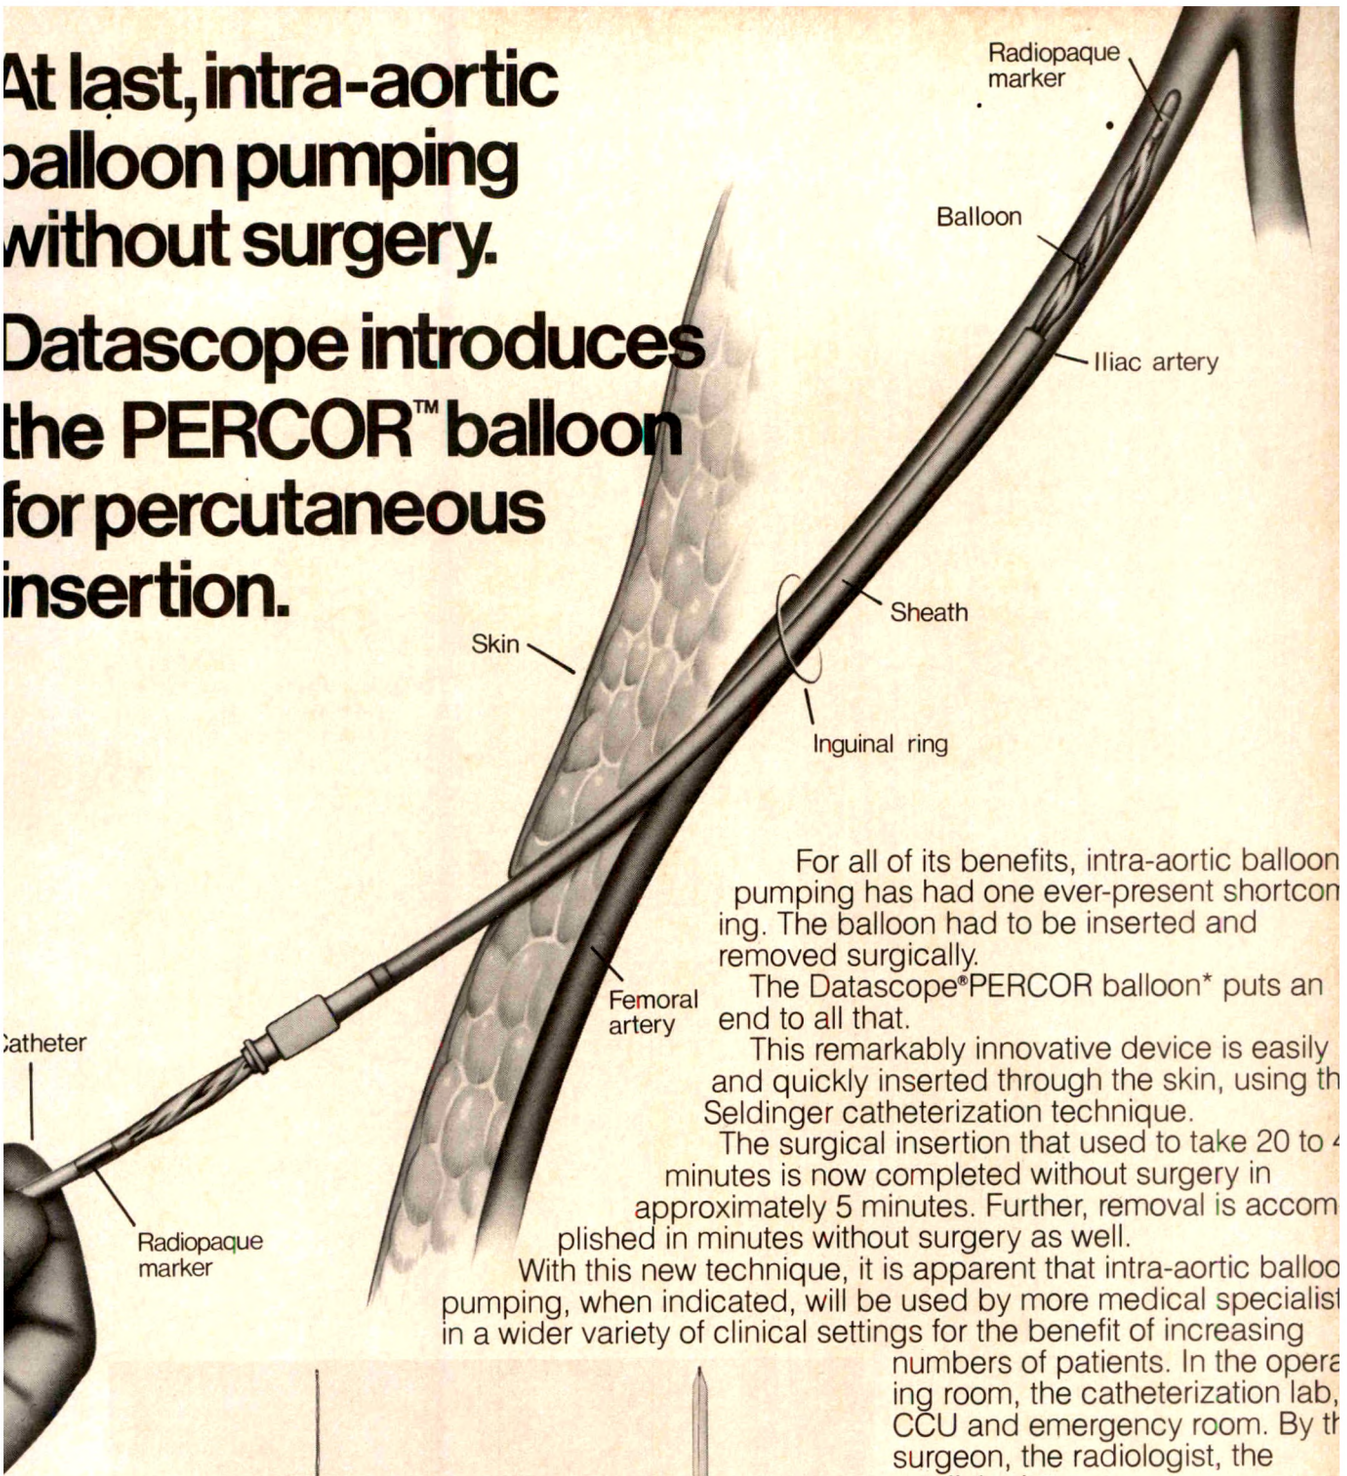
At last, intra-aortic balloon pumping without surgery.

Datascope introduces the PERCOR™ balloon for percutaneous insertion.



For all of its benefits, intra-aortic balloon pumping has had one ever-present shortcoming. The balloon had to be inserted and removed surgically.

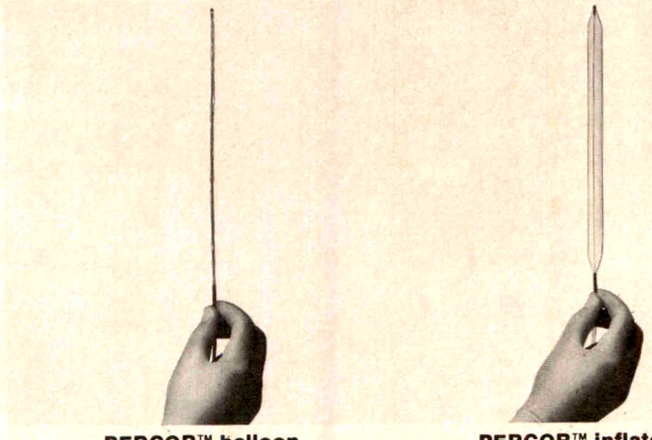
The Datascope®PERCOR balloon* puts an end to all that.

This remarkably innovative device is easily and quickly inserted through the skin, using the Seldinger catheterization technique.

The surgical insertion that used to take 20 to 4 minutes is now completed without surgery in approximately 5 minutes. Further, removal is accomplished in minutes without surgery as well.

With this new technique, it is apparent that intra-aortic balloon pumping, when indicated, will be used by more medical specialists in a wider variety of clinical settings for the benefit of increasing numbers of patients. In the operating room, the catheterization lab, CCU and emergency room. By the surgeon, the radiologist, the cardiologist.

We would be pleased to send you more information about our revolutionary device and to schedule a filmed demonstration of its use. Call Robert Rewolinski, Manager, Cardiac Assist Products, at 201-265-8800 or write him at Datascope Corp., Dept. #5-S, 580 Winters Avenue, Paramus, NJ 07652.



PERCOR™ balloon ready for insertion.

PERCOR™ inflated.

The Datascope PERCOR™ intra-aortic balloon

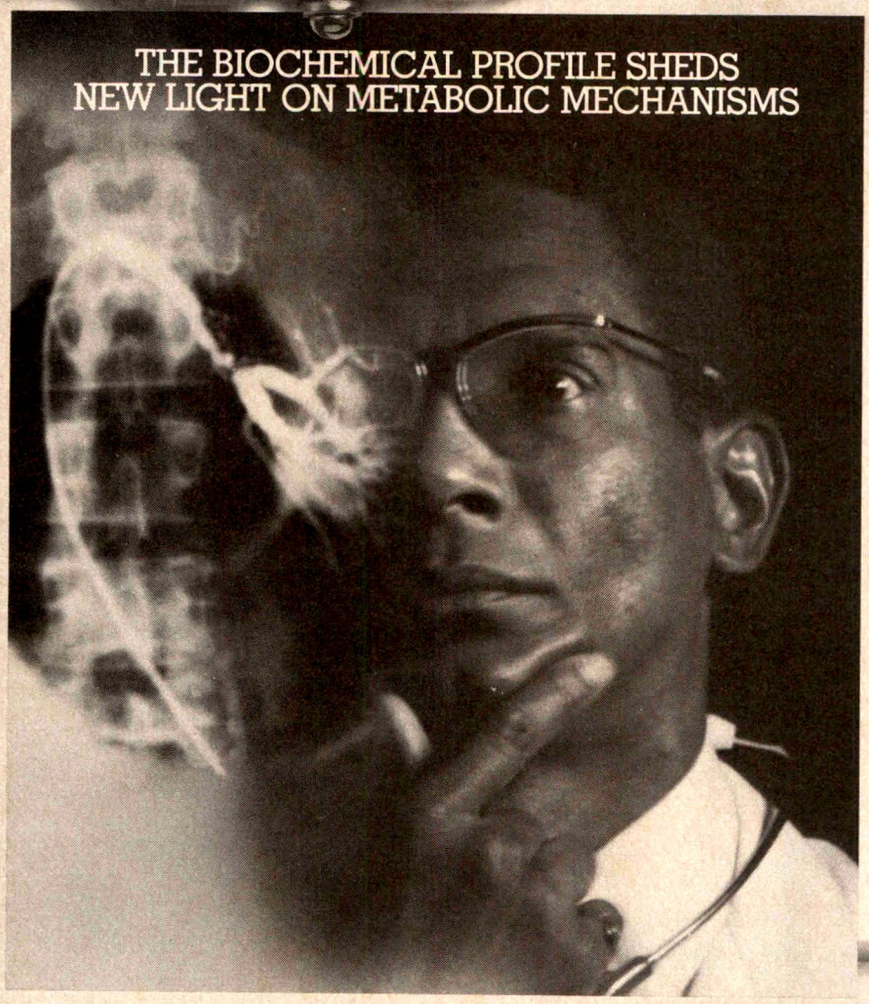
"PROFILING" TODAY'S HYPERTENSIVE PATIENT



THE BIOCHEMICAL PROFILE SHEDS NEW LIGHT ON METABOLIC MECHANISMS

While hypertension still remains an enigma, its metabolic pathways have become clearer in the past twenty years. One of the most important pathways involves the renin-angiotensin-aldosterone system. The kidney is known to secrete renin under three circumstances: 1) when the organ itself becomes ischemic; 2) when the body's sodium content is depressed; 3) when blood volume is reduced. Renin then catalyzes the conversion of the decapeptide angiotensin I to the octapeptide angiotensin II. Besides being the most potent vasopressor known,[1] angiotensin II also stimulates the adrenal gland to produce aldosterone. By enhancing renal reabsorption of sodium, aldosterone expands the body's sodium content and plasma volume. This reduces renin production and closes the loops of the negative feedback system. A breakdown in this system may result in higher levels of renin and angiotensin II—and sustained high blood pressure.

Disturbances in other mechanisms can also trigger metabolic chains of events that lead to hypertension. This increasing knowledge has generated interest in drugs designed to halt the hypertensive process at several points. One of the newest drugs is thought to inhibit the enzyme that converts angiotensin I into angiotensin II.[1] Equally important has been the development of more accurate diagnostic tests for "biochemical" profiling.

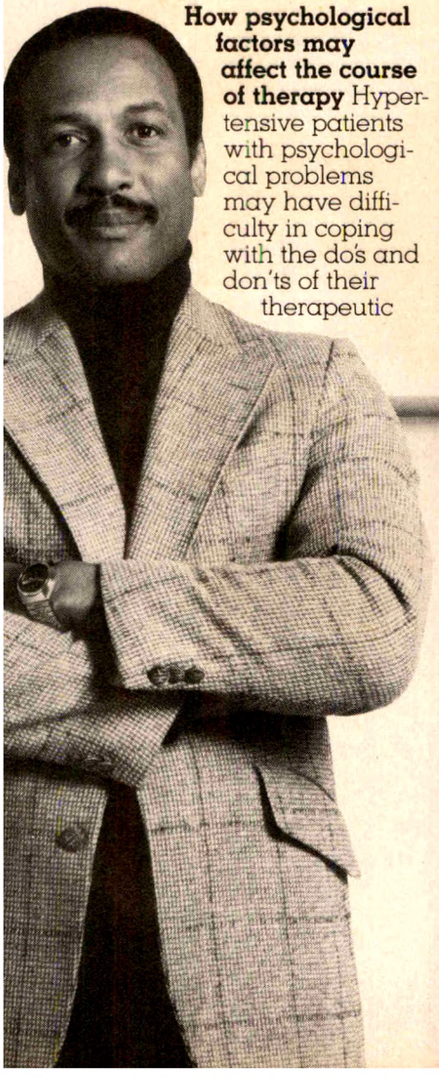
How useful is measuring renin activity? Some clinicians now advocate "renin profiling" of all hypertensives. This rather complicated test provides the renin-sodium index by indirectly measuring the renin level and comparing it to sodium intake. The index helps distinguish renin-dependent hypertensives (about 70% of patients) from those who are sodium-dependent. It is only the latter who are most likely to benefit from diuretics and the "stepped-care" approach.

While renin profiling can be very useful for selected patients, most physicians consider it unnecessary or impractical for routine evaluation. The initial choice of therapy rarely hinges on renin activity.[2] Also, the renin-sodium index is hard to obtain in non-hospitalized patients and may not offer any real advantages over a therapeutic trial that includes a diuretic (for low-renin patients) or a beta blocker (for high-renin patients).[2,3]

The lab workup that works for most patients Some authorities believe that a minimal workup is sufficient for roughly 90% of hypertensive patients.[3] This generally includes a hematologic profile, urinalysis, blood chemistry (covering a number of biochemical variables), along with the standard ECG and chest roentgenogram.[2,3] More exhaustive tests—including renal profiling, intravenous urograms and catecholamine level determinations—would only be ordered if secondary causes are suspected.

THE "PSYCHOLOGICAL PROFILE" ADDS VALUABLE INSIGHTS

At times, it reveals excessive anxiety A good deal of research has focused on the contributory role of psychological and social factors in the development of hypertension. Such factors have been found to increase plasma renin activity.[4] Consequently it is often recommended that some form of psychosocial profile be added to the patient's family and medical history.[2,5] Even though the hypertensive patient may seem calm, a few carefully worded questions often uncover intense psychic tension. The patient's anxiety may center on his psychological problems alone or may extend to the economic and social repercussions of his illness.



How psychological factors may affect the course of therapy Hypertensive patients with psychological problems may have difficulty in coping with the do's and don'ts of their therapeutic program... and with demoralizing new self-images as "chronically sick, potentially dependent" persons. The psychological profile helps the physician assess the patient's understanding of his illness, his emotional reactions to it, and the likelihood of his compliance with recommended therapy. This information can help set the stage for the mutually rewarding doctor-patient rapport essential to successful long-term management of any chronic illness.

Why Valium®(diazepam/Roche) can be valuable adjunctive therapy In many cases, your reassurance and continued support will be enough to relieve your patient's emotional distress. But for some patients, you may find that specific antianxiety medication is also warranted. It is at these times that Valium can be especially helpful. Valium works promptly and predictably to relieve the excessive psychic tension that often accompanies organic illness. Initial calming typically occurs within hours—more sustained and extensive symptomatic relief becomes manifest in a matter of days. With intense anxiety under control, the hypertensive patient is often better able to face his condition and to comply with your treatment program. Another important factor—Valium (diazepam/Roche) is used with most primary medications, including cardiac glycosides, diuretics and vasodilators.

Side effects more serious than drowsiness, fatigue and ataxia are rare and seldom severe. As with all CNS-acting agents, patients should be cautioned against drinking alcoholic beverages or driving. Periodic reassessment of the continued need for psychotropic medication is also recommended. Once the patient is again able to cope, Valium should be gradually discontinued. See guidelines on following page for further ways to optimize therapy with Valium.

VALIUM® (IV)

diazepam/Roche

2-mg, 5-mg, 10-mg scored tablets

WHEN ANXIETY DISORDERS HAMPER HIS ABILITY TO COPE

Before prescribing, please see brief summary of product information on following page.

ROCHE®

VALIUM® (IV) diazepam/Roche

Before prescribing, please consult complete product information, a summary of which follows:
Indications: Management of anxiety disorders, or short-term relief of symptoms of anxiety; symptomatic relief of acute agitation, tremor, delirium tremens and hallucinosis due to acute alcohol withdrawal; adjunctively in skeletal muscle spasm due to reflex spasm to local pathology; spasticity caused by upper motor neuron disorders; athetosis; stiff-man syndrome; convulsive disorders (not for sole therapy).
The effectiveness of Valium in long-term use, that is, more than 4 months, has not been assessed by systematic clinical studies. The physician should periodically reassess the usefulness of the drug for the individual patient.
Contraindicated: Known hypersensitivity to the drug. Children under 6 months of age. Acute narrow angle glaucoma; may be used in patients with open angle glaucoma who are receiving appropriate therapy.
Warnings: Not of value in psychotic patients. Caution against hazardous occupations requiring complete mental alertness. When used adjunctively in convulsive disorders, possibility of increase in frequency and/or severity of grand mal seizures may require increased dosage of standard anticonvulsant medication; abrupt withdrawal may be associated with temporary increase in frequency and/or severity of seizures. Advise against simultaneous ingestion of alcohol and other CNS depressants. Withdrawal symptoms similar to those with barbiturates and alcohol have been observed with abrupt discontinuation, usually limited to extended use and excessive doses. Infrequently, milder withdrawal symptoms have been reported following abrupt discontinuation of benzodiazepines after continuous use, generally at higher therapeutic levels, for at least several months. After extended therapy, gradually taper dosage. Keep addiction-prone individuals under careful surveillance because of their predisposition to habituation and dependence.

Usage in Pregnancy: **Use of minor tranquilizers during first trimester should almost always be avoided because of increased risk of congenital malformations as suggested in several studies. Consider possibility of pregnancy when instituting therapy; advise patients to discuss therapy if they intend to or do become pregnant.**

Precautions: If combined with other psychotropics or anticonvulsants, consider carefully pharmacology of agents employed; drugs such as phenothiazines, narcotics, barbiturates, MAO inhibitors and other antidepressants may potentiate its action. Usual precautions indicated in patients severely depressed, or with latent depression, or with suicidal tendencies. Observe usual precautions in impaired renal or hepatic function. Limit dosage to smallest effective amount in elderly and debilitated to preclude ataxia or oversedation.
Side Effects: Drowsiness, confusion, diplopia, hypotension, changes in libido, nausea, fatigue, depression, dysarthria, jaundice, skin rash, ataxia, constipation, headache, incontinence, changes in salivation, slurred speech, tremor, vertigo, urinary retention, blurred vision. Paradoxical reactions such as acute hyperexcited states, anxiety, hallucinations, increased muscle spasticity, insomnia, rage, sleep disturbances, stimulation have been reported; should these occur, discontinue drug. Isolated reports of neutropenia, jaundice; periodic blood counts and liver function tests advisable during long-term therapy.
Dosage: Individualize for maximum beneficial effect. *Adults:* Anxiety disorders, symptoms of anxiety, 2 to 10 mg b.i.d. to q.i.d.; alcoholism, 10 mg t.i.d. or q.i.d. in first 24 hours, then 5 mg t.i.d. or q.i.d. as needed; adjunctively in skeletal muscle spasm, 2 to 10 mg t.i.d. or q.i.d.; adjunctively in convulsive disorders, 2 to 10 mg b.i.d. to q.i.d. *Geriatric or debilitated patients:* 2 to 2½ mg, 1 or 2 times daily initially, increasing as needed and tolerated. (See Precautions.) *Children:* 1 to 2½ mg t.i.d. or q.i.d. initially, increasing as needed and tolerated (not for use under 6 months).
Supplied: Valium® (diazepam/Roche) Tablets, 2 mg, 5 mg and 10 mg—bottles of 100 and 500; Tel-E-Dose® packages of 100, available in trays of 4 reverse-numbered boxes of 25, and in boxes containing 10 strips of 10; Prescription Paks of 50, available in trays of 10.

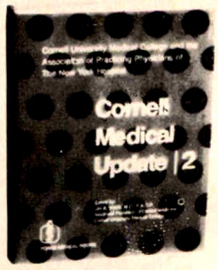
Now in book form...the latest Update Your Medicine lectures.

CORNELL MEDICAL UPDATE/2



Edited by LILA A. WALLIS, MD, FACP

Helps you keep up with the new advances in your specialty in the comfort of your home or office.

All new material—specialties expanded.

The workbook format of the CORNELL MEDICAL UPDATE/2 breaks medical publishing traditions by giving practicing physicians a quick overview of the latest advances in their specialty. It transcribes the Update Your Medicine lectures sponsored by New York Hospital-Cornell Medical Center. These lectures are well-known for helping physicians prepare for Recertification despite the demands of a heavy practice

The new approach of the first volume was so well-received that it went through three printings in less than two years. Now the just published CORNELL MEDICAL UPDATE/2 takes up where the first volume left off. It has been specially designed for the practicing physician who has difficulty keeping up with the growing literature of the field. Each chapter transcribes one of the lectures and covers a specific speciality in-depth from basic physiologic and chemical principles to its clinical applications.

Lila A. Wallis, MD, FACP, the series editor, has eliminated all the filler material a *continuing* education does not need. You won't find historical reviews or a rehash of material you've known since medical school. You will find the practical, life-saving knowledge a dynamic practice depends on. Because the lectures have been edited for easy reading and laid out for quick comprehension, you'll be able to incorporate all the material into your own professional technique.

Earn 25 Credits Towards AMA Physician's Recognition Award. CORNELL MEDICAL UPDATE/2 has been approved for Category 1 credit towards the AMA's Physician's Recognition Award for Continuing Medical Education. Full details on how to apply for credit are included with every copy.

Yorke Medical Books, 666 5th Ave., N.Y., N.Y. 10103 AJC-3/81

Please send me a copy of CORNELL MEDICAL UPDATE/2 at $38.00. I may use the book for 30 days and if not completely satisfied, return it for full refund or credit.

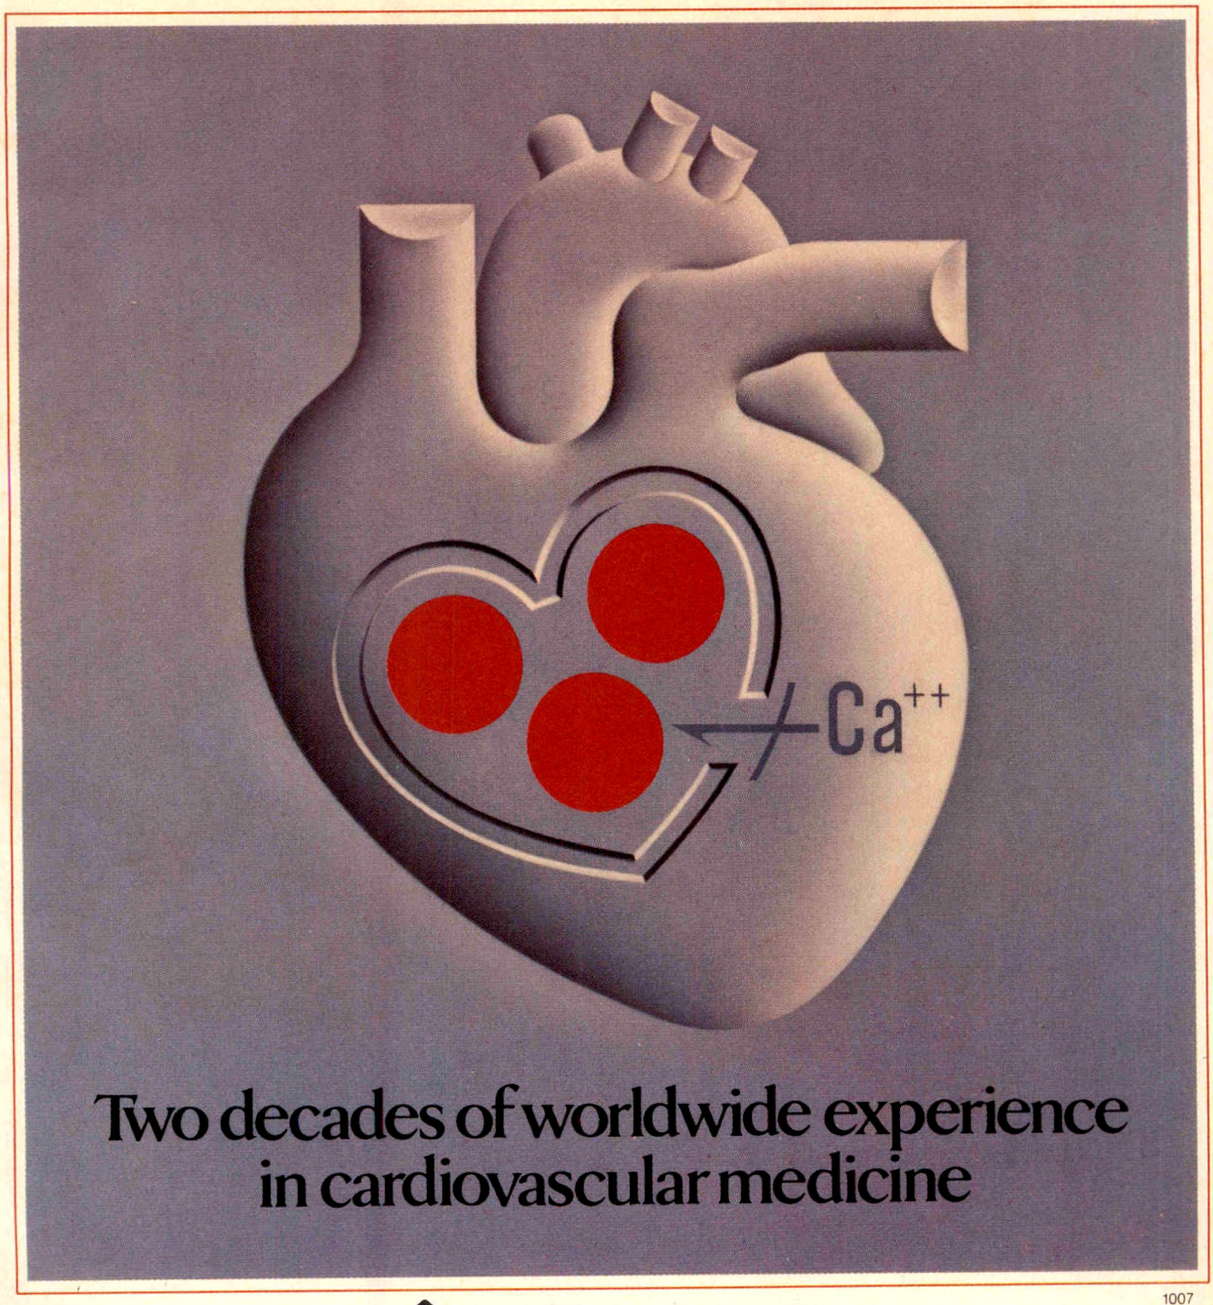
KNOLL

The pioneer in the development of calcium ion antagonists



Two decades of worldwide experience in cardiovascular medicine

1007

knoll®
KNOLL PHARMACEUTICAL COMPANY
Whippany, New Jersey 07981

THE TRENDSETTER™ — The top-of-the-line scanner for integrated ECG, blood pressure and pacemaker evaluation, together with comprehensive alphanumeric/graphic summaries.

VIS-U-SCAN™ — The high-speed system that puts 24 hours of ECG in your hands in three minutes flat without missing a beat.

SMART SCANNERS, SMART VALUES

There's a Del Mar Avionics ECG scanner that satisfies your most exacting requirements — in the hospital or in your office. And a worldwide network of servic centers assures fast, professional response when you need it, where you need it.

An outstanding Education and Training staff rounds out our commitment to excellence. Training courses extend the skills and knowledge of your staff in the appl cation of ECG principles to Holter System data analysis.

Our full line of smart scanners coupled with the extra services only a leader can provide, makes your investment in a Del Mar Avionics system a smart move. Ca your local representative today.

MODEL 633/ 636A— The compact Holter scanning system handles the workload right in your office. Two channels of data with memory-scope display make it fast, flexible and easy-to-use.

THE EVALUATOR,™ NEW!— The middle-of-the-line Holter ECG scanner— microprocessor-controlled, features "smart" arrhythmia analyzer.

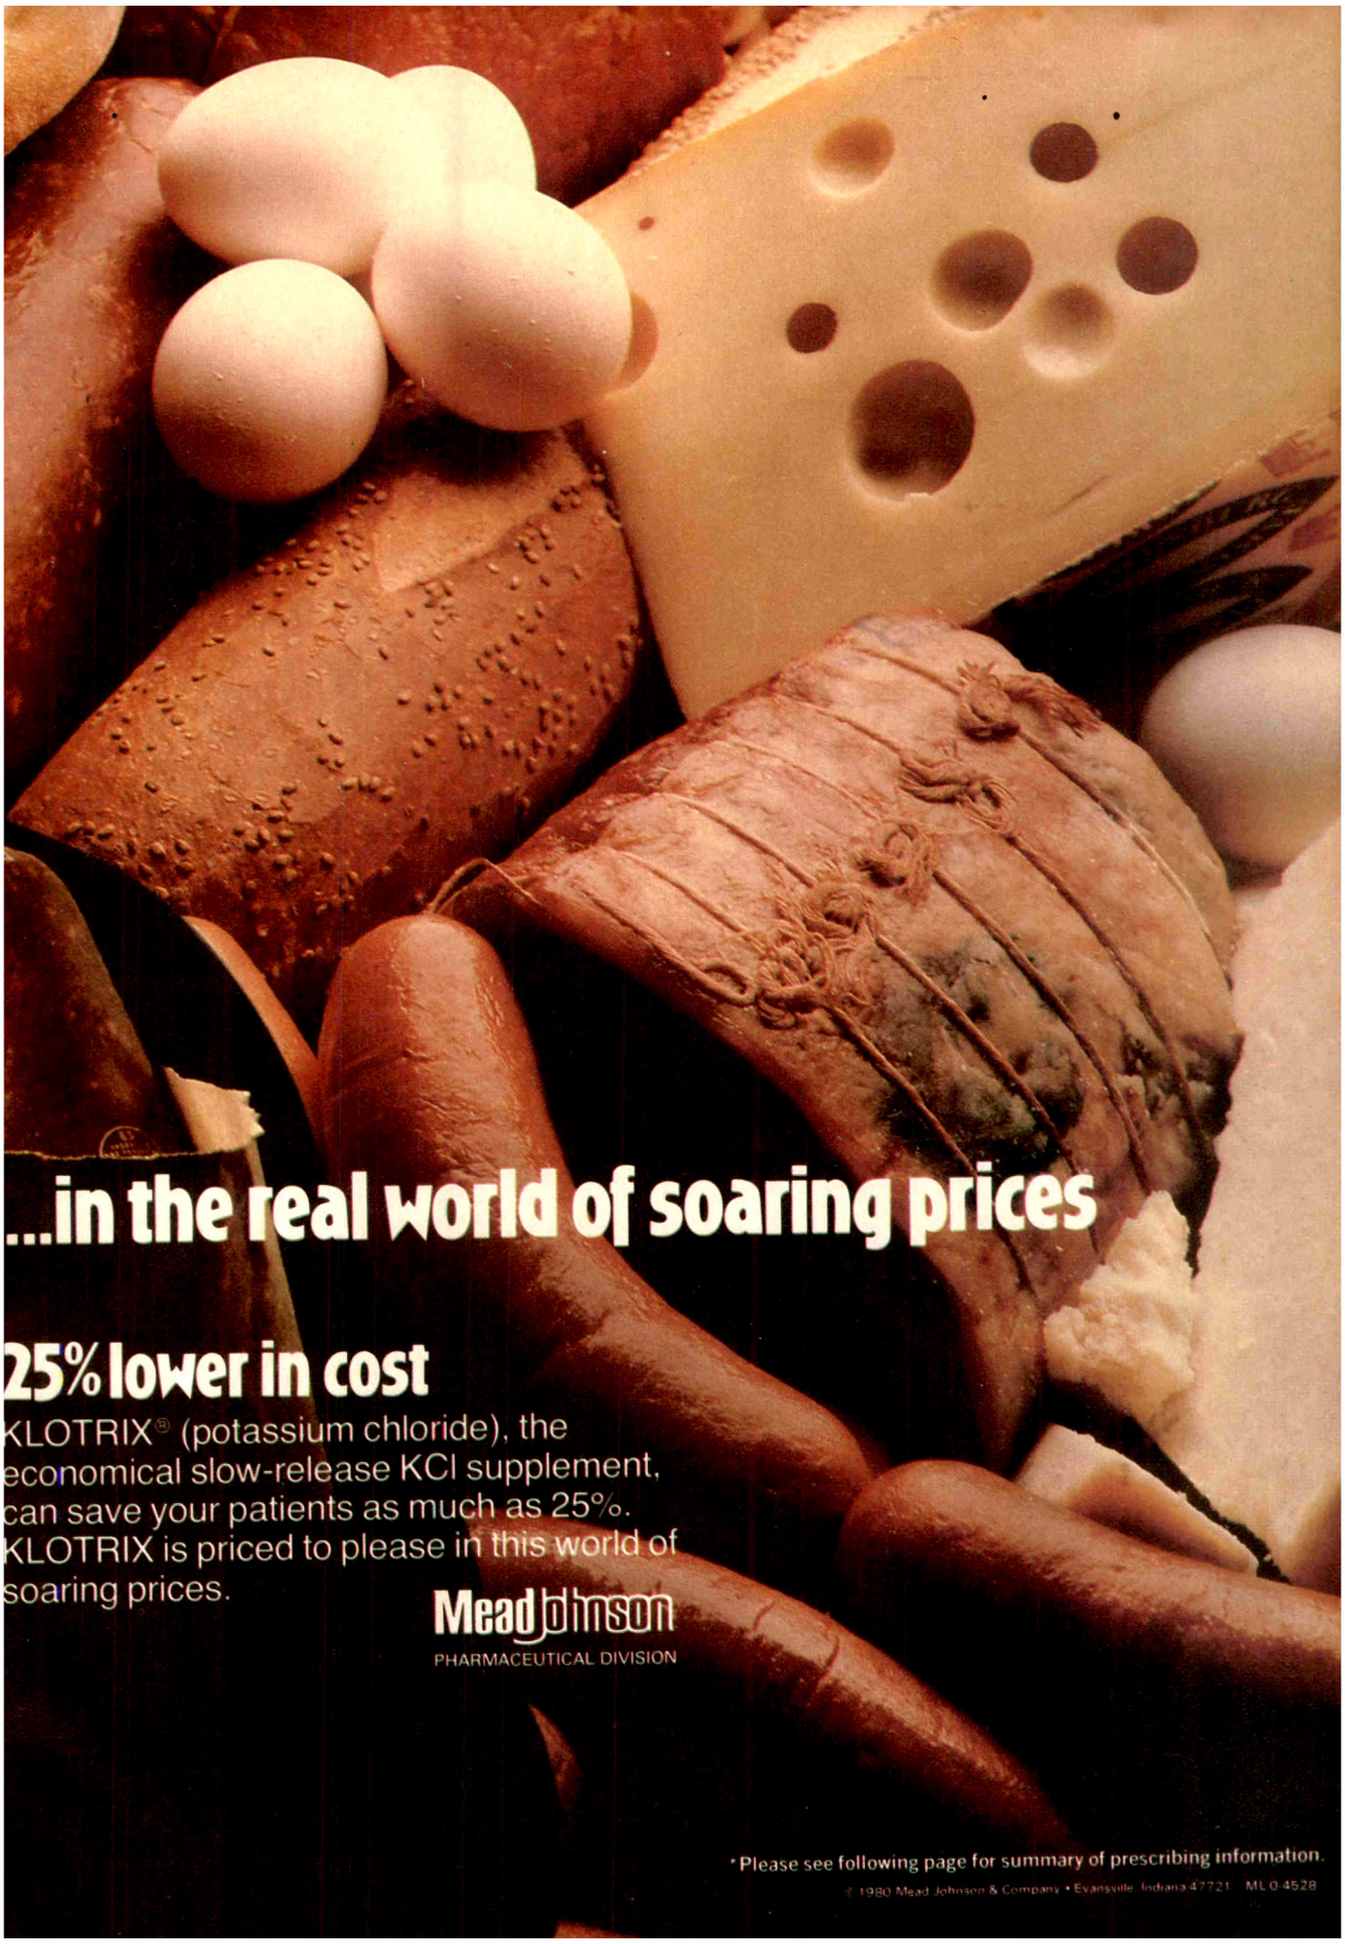
NEW
KLOTRIX®
[POTASSIUM CHLORIDE]
SLOW-RELEASE
TABLETS 10 mEq
For real people with compliance problems
once a day for prophylaxis–
twice a day for therapy*
KLOTRIX has more potassium chloride than sugar-coated slow-release KCl tablets. This means fewer tablets per day for better patient compliance. The KLOTRIX regimen fits into the busy lives of real people.



...in the real world of soaring prices
25% lower in cost
KLOTRIX® (potassium chloride), the economical slow-release KCl supplement, can save your patients as much as 25%. KLOTRIX is priced to please in this world of soaring prices.

NEW KLOTRIX®

(POTASSIUM CHLORIDE)
SLOW-RELEASE TABLETS 10 mEq

DESCRIPTION KLOTRIX is a film-coated (not enteric-coated) tablet containing 750 mg potassium chloride (equivalent to 10 mEq) in a wax matrix. This formulation is intended to provide a controlled release of potassium from the matrix to minimize the likelihood of producing high localized concentrations of potassium within the gastrointestinal tract.

INDICATIONS— BECAUSE OF REPORTS OF INTESTINAL AND GASTRIC ULCERATION AND BLEEDING WITH SLOW-RELEASE POTASSIUM CHLORIDE PREPARATIONS, THESE DRUGS SHOULD BE RESERVED FOR THOSE PATIENTS WHO CANNOT TOLERATE OR REFUSE TO TAKE LIQUID OR EFFERVESCENT POTASSIUM PREPARATIONS OR FOR PATIENTS IN WHOM THERE IS A PROBLEM OF COMPLIANCE WITH THESE PREPARATIONS.

1. For therapeutic use in patients with hypokalemia with or without metabolic alkalosis; in digitalis intoxication and in patients with hypokalemic familial periodic paralysis.
2. For prevention of potassium depletion when the dietary intake of potassium is inadequate in the following conditions: Patients receiving digitalis and diuretics for congestive heart failure; hepatic cirrhosis with ascites; states of aldosterone excess with normal renal function; potassium-losing nephropathy, and certain diarrheal states.
3. The use of potassium salts in patients receiving diuretics for uncomplicated essential hypertension is often unnecessary when such patients have a normal dietary pattern. Serum potassium should be checked periodically, however, and, if hypokalemia occurs, dietary supplementation with potassium-containing foods may be adequate to control milder cases. In more severe cases supplementation with potassium salts may be indicated.

CONTRAINDICATIONS In patients with hyperkalemia, since a further increase in serum potassium concentration in such patients can produce cardiac arrest. Hyperkalemia may complicate any of the following conditions: chronic renal failure, systemic acidosis such as diabetic acidosis, acute dehydration, extensive tissue breakdown as in severe burns, adrenal insufficiency, or the administration of a potassium-sparing diuretic (*eg,* spironolactone, triamterene).

Wax-matrix potassium chloride preparations have produced esophageal ulceration in certain cardiac patients with esophageal compression due to enlarged left atrium.

All solid dosage forms of potassium supplements are contraindicated in any patient in whom there is cause for arrest or delay in tablet passage through the G.I. tract. In these instances, potassium supplementation should be with a liquid preparation.

WARNINGS Hyperkalemia: In patients with impaired mechanisms for excreting potassium, administration of potassium salts can produce hyperkalemia and cardiac arrest. This occurs most commonly in patients given potassium intravenously but may also occur when given orally. Potentially fatal hyperkalemia can develop rapidly and be asymptomatic. Use of potassium salts in patients with chronic renal disease, or any other condition which impairs potassium excretion requires particularly careful monitoring of the serum potassium concentration and appropriate dosage adjustment.

Interaction with potassium-sparing diuretics: Hypokalemia should not be treated by the concomitant administration of potassium salts and a potassium-sparing diuretic (*eg,* spironolactone or triamterene), since the simultaneous administration of these agents can produce severe hyperkalemia.

Gastrointestinal lesions: Potassium chloride tablets have produced stenotic and/or ulcerative lesions of the small bowel and deaths. These lesions are caused by a high localized concentration of potassium ion in the region of a rapidly dissolving tablet, which injures the bowel wall and thereby produces obstruction, hemorrhage, or perforation. KLOTRIX is a wax-matrix tablet formulated to provide a controlled rate of release of potassium chloride and thus to minimize the possibility of a high local concentration of potassium ion near the bowel wall. While the reported frequency of small-bowel lesions is much less with wax-matrix tablets (less than one per 100,000 patient-years) than with enteric-coated potassium chloride tablets (40-50 per 100,000 patient-years) cases associated with wax-matrix tablets have been reported both in foreign countries and in the United States. In addition, perhaps because the wax-matrix preparations are not enteric-coated and release potassium in the stomach, there have been reports of upper gastrointestinal bleeding associated with these products. The total number of gastrointestinal lesions remains less than one per 100,000 patient-years. KLOTRIX should be discontinued immediately and the possibility of bowel obstruction or perforation considered if severe vomiting, abdominal pain, distention, or gastrointestinal bleeding occurs.

Metabolic acidosis: Hypokalemia in patients with metabolic *acidosis* should be treated with an alkalinizing potassium salt such as potassium bicarbonate, potassium citrate, or potassium acetate.

PRECAUTIONS Potassium depletion is ordinarily diagnosed by demonstrating hypokalemia in a patient with a clinical history suggesting some cause for potassium depletion. In interpreting the serum potassium level, the physician should bear in mind that acute alkalosis *per se* can produce hypokalemia in the absence of a deficit in total body potassium, while acute acidosis *per se* can increase the serum potassium concentration into the normal range even in the presence of a reduced total body potassium. Treatment of potassium depletion particularly in presence of cardiac disease, renal disease, or acidosis, requires careful attention to acid-base balance and appropriate monitoring of serum electrolytes, electrocardiogram and clinical status of patient.

ADVERSE REACTIONS Most common to oral potassium salts: nausea, vomiting, abdominal discomfort, and diarrhea. These symptoms are due to irritation of the gastrointestinal tract and are best managed by diluting the preparation further, taking the dose with meals, or reducing the dose. One of the most severe adverse effects is hyperkalemia (see Contraindications and Warnings). There also have been reports of upper and lower gastrointestinal conditions including obstruction, bleeding, ulceration and perforation (see Contraindications and Warnings); other factors known to be associated with such conditions were present in many of these patients. Skin rash has been reported rarely.

DOSAGE Usual dietary intake potassium by the average adult is 40 to 80 mEq per day. Potassium depletion sufficient to cause hypokalemia usually requires loss of 200 or more mEq of potassium from the total body store.

Dosage must be adjusted to the individual needs of each patient but is typically in the range of 20 mEq per day for prevention of hypokalemia to 40-100 mEq per day or more for treatment of potassium depletion.

Note: KLOTRIX slow-release tablets must be swallowed whole and never crushed or chewed.

HOW SUPPLIED Bottles of 100.

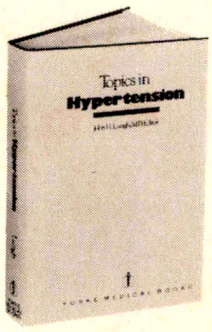
Laragh's eagerly awaited new book on the silent killer

TOPICS IN HYPERTENSION



Edited by

John H. Laragh, MD

Master Professor of Medicine
Director, The Cardiovascular Center Chief, Cardiology Division The New York Hospital-Cornell Medical Center

644 pages. 36 chapters by 85 internationally known specialists. Illustrated. Comprehensively indexed. $49.00. Available on 30-day approval.

High blood pressure is no longer only a problem of worldwide interest and relevance. It is now one in which the knowledge base has exploded to the point where the informed physician can do more and more about it in his daily practice...and can apply, to an ever-increasing extent, more sophisticated and individually tailored therapies.

Laragh's TOPICS IN HYPERTENSION places this kind of vital knowledge within instant reach of the physician. It presents a carefully selected array of discussions. It deals in depth with recent breakthroughs in understanding, diagnosing, and treating this problem.

This book is conveniently organized for effective consultation and reading:

- **Section 1** considers recently maturing biochemical and pathophysiologic aspects of the problem.
- **Section 2** deals with new physiologic approaches to diagnosis.
- **Section 3** discusses new perceptions of the clinical and prognostic aspects of hypertension.
- **Section 4** considers in detail the more recently introduced modes of therapy. These new agents presage the beginning of a new era of more selective and specific therapy for increasing numbers of patients.

Antiarrhythmia Bulletin No. 2

Quinidine Withdrawal or Replacement May Decrease Physiologic Effect of Digoxin

Some Further Reports on Problems Arising From the Quinidine-Digoxin Interaction

"An increase in serum digoxin concentration after quinidine is added is now anticipated by many physicians. The opposite is predictable from this observation: a fall in the serum concentration and physiologic effect of digoxin when quinidine is withdrawn from a patient previously stable on both drugs. Although an example of this fall has been reported, little emphasis has been given to this aspect of the quinidine-digoxin interaction, which may have important consequences....

"It appears that this [a 62-year-old female] patient's symptoms and increase in ventricular rate were due to a decrease in serum digoxin concentration and physiologic effect caused by withdrawal of quinidine. This phenomenon should be anticipated when quinidine is discontinued or replaced by other antiarrhythmic therapy in patients previously stable on digoxin and quinidine, especially those in atrial fibrillation, and may require an appropriate readjustment of digoxin dosage based on clinical observations and measured serum digoxin concentrations."

—From Moench, T.R.: The Quinidine-Digoxin Interaction, N. Engl. J. Med. *302*:864, 1980.

"Dr. Moench reports a case that supports the view that quinidine withdrawal can decrease the effect of digoxin. The end point in his study was the time-honored ventricular response to atrial fibrillation, i.e., atrioventricular nodal conduction. His case report provides another bit of evidence that the change in serum digoxin concentration during the interaction often reflects the effect of digoxin on the heart. This hypothesis is difficult to test, and the observations of Dr. Moench are helpful in view of the increasingly complex picture of the interaction."

—From Bigger, J.T., Jr.: The Quinidine-Digoxin Interaction, N. Engl. J. Med. *302*:864–865, 1980.

Do Other Antiarrhythmics Interact With Digoxin?

"We compared the effects of quinidine and three alternate antiarrhythmic drugs on serum digoxin concentration in 63 patients before and during administration of quinidine, procainamide, disopyramide, or mexiletine. Quinidine increased digoxin concentration by at least 0.5 nmol/L in 21 of 22 patients: Mean serum digoxin rose from 1.2 nmol/L to 2.4 nmol/L ($P<0.001$). Procainamide, disopyramide, or mexiletine increased serum digoxin by 0.5 nmol/L in one of 41 patients. Anorexia, nausea, and vomiting developed soon after starting quinidine therapy in 10 of the 22 patients who received quinidine but in only five of the 41 patients who received procainamide, disopyramide, or mexiletine ($P<0.01$). Quinidine prolonged the PR interval from 160 ± 14 ms to 183 ± 26 ms, but procainamide, disopyramide, and mexiletine did not change the PR interval ($P < 0.005$). In digitalized patients, quinidine increases serum digoxin concentration, increases digoxin's effect on atrioventricular conduction, and produces more adverse gastrointestinal effects than procainamide, disopyramide, or mexiletine....

"Figure 1 shows the change in serum digoxin concentrations during administration of the four antiarrhythmic drugs. Each dot represents, for one patient, the difference between the mean serum digoxin concentration before and during therapy with quinidine, procainamide, disopyramide, or mexiletine....

"Because interaction between digoxin and quinidine is common and because quinidine's potential for producing toxicity is still unknown, we recommend that caution be exercised when quinidine is given to digitalized patients....

"Our study shows that several other orally active antiarrhythmic drugs fail to cause an increase in serum digoxin concentration."

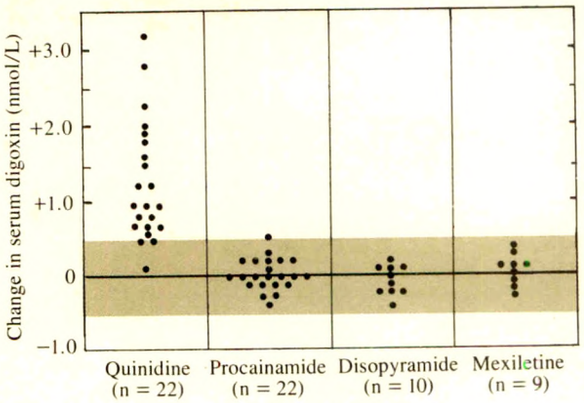

Figure 1.

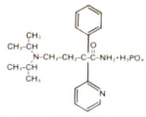
—From Leahey, E.B., Jr., and others: The Effect of Quinidine and Other Oral Antiarrhythmic Drugs on Serum Digoxin: A Prospective Study, Ann. Intern. Med. *92*:605–608, 1980.

From what has appeared in the literature concerning the elevation of digoxin levels with concomitant quinidine use and reported lack of elevation of digoxin levels with concomitant Norpace® (disopyramide phosphate) use, it would appear that Norpace could be a logical alternative to quinidine in some patients using digoxin concomitantly.

NORPACE® CAPSULES (disopyramide phosphate)

DESCRIPTION

Norpace (disopyramide phosphate) is an antiarrhythmic drug available for oral administration in capsules containing 100 mg or 150 mg of disopyramide base, present as the phosphate. The base content of the phosphate salt is 77.6%. The structural formula of Norpace is seen at the right. Norpace is freely soluble in water, and the free base (pKa 8.36) has an aqueous solubility of 1 mg/ml. The chloroform water partition coefficient of the base is 3.1 at pH 7.2. Norpace is a racemic mixture of *d*- and *l*-isomers. This drug is not chemically related to other antiarrhythmic drugs.



α-[2-(diisopropylamino) ethyl]-α-phenyl-2-pyridineacetamide phosphate

CLINICAL PHARMACOLOGY

Mechanisms of action: Norpace (disopyramide phosphate) is a Type 1 antiarrhythmic drug (i.e., similar to procainamide and quinidine). *In animal studies* Norpace decreases the rate of diastolic depolarization (phase 4) in cells with augmented automaticity; decreases the upstroke velocity (phase 0) and increases the action potential duration of normal cardiac cells; decreases the disparity in refractoriness between infarcted and adjacent normally perfused myocardium and has no effect on alpha- or beta-adrenergic receptors.

Electrophysiology: In man, Norpace at therapeutic plasma levels shortens the sinus node recovery time; lengthens the effective refractory period of the atrium and has a minimal effect on the effective refractory period of the AV node. Little effect has been shown on AV-nodal and His-Purkinje conduction times or QRS duration. However, prolongation of conduction in accessory pathways occurs.

Hemodynamics: At recommended oral doses, Norpace rarely produces significant alterations of blood pressure in patients without congestive heart failure (see *Warnings*). Intravenous injection (2 mg/kg over 3 minutes) produces a moderate, transient increase in heart rate and in total peripheral resistance. In patients with organic heart disease intravenous Norpace causes cardiac depression, with approximately a 10% reduction of cardiac output.

Anticholinergic activity: The *in vitro* anticholinergic activity of Norpace is approximately 0.06% that of atropine; however, the usual dose of Norpace is 150 mg every 6 hours compared to 0.4-0.6 mg for atropine (see *Warnings* and *Adverse Reactions* for anticholinergic side effects).

Pharmacokinetics: Following oral administration disopyramide phosphate is rapidly and almost completely absorbed, and peak plasma levels are usually attained within two hours. The usual therapeutic plasma levels of disopyramide *free base* are 2-4 mcg/ml and at these concentrations protein binding varies from 50-65%. Because of concentration-dependent protein binding, it is difficult to predict the concentration of the free drug when total drug is measured.

The mean plasma half-life of disopyramide in healthy humans is 6.7 hours (range of 4 to 10 hours). In six patients with impaired renal function (creatinine clearance less than 40 ml/min), disopyramide half-life values were 8 to 18 hours.

In healthy men about 50% of a given dose of disopyramide is excreted in the urine as the unchanged drug, about 20% as the mono-N-dealkylated metabolite and 10% as the other metabolites. The plasma concentration of the major metabolite is approximately one tenth that of disopyramide. Altering the urinary pH in man does not affect the plasma half-life of disopyramide.

INDICATIONS

Norpace should be prescribed only after appropriate electrocardiographic assessment.

Norpace (disopyramide phosphate) is indicated for suppression and prevention of recurrence of the following cardiac arrhythmias when they occur singly or in combination:

1. Unifocal premature (ectopic) ventricular contractions.
2. Premature (ectopic) ventricular contractions of multifocal origin.
3. Paired premature ventricular contractions (couplets).
4. Episodes of ventricular tachycardia (persistent ventricular tachycardia is ordinarily treated with D.C. cardioversion).

In controlled trials of ambulatory patients Norpace was as effective as 325 mg quinidine q 6 h in reducing the frequency of ventricular ectopic activity. Norpace was equally effective in digitalized and nondigitalized patients. Norpace is also equally effective in the treatment of primary cardiac arrhythmias and those which occur in association with organic heart disease including coronary artery disease.

Oral Norpace (disopyramide phosphate) has not been adequately studied in patients with acute myocardial infarction or in patients with persistent ventricular tachycardia or atrial arrhythmias.

Type 1 antiarrhythmic drugs are usually not effective in treating arrhythmias secondary to digitalis intoxication and, therefore, Norpace is not indicated for such cases.

The value of antiarrhythmic drugs in preventing sudden death in patients with serious ventricular ectopic activity has not been established.

CONTRAINDICATIONS

Norpace (disopyramide phosphate) is contraindicated in the presence of cardiogenic shock, preexisting second- or third-degree AV block (if no pacemaker is present), or known hypersensitivity to the drug.

WARNINGS

Negative inotropic properties: Heart failure/hypotension: **Norpace may cause or worsen congestive heart failure or produce severe hypotension as a consequence of its negative inotropic properties. Hypotension has been observed primarily in patients with primary cardiomyopathy or inadequately compensated congestive heart failure. Norpace should not be used in patients with uncompensated or marginally compensated congestive heart failure or hypotension unless the congestive heart failure or hypotension is secondary to cardiac arrhythmia. Patients with a history of heart failure may be treated with Norpace, but careful attention must be given to the maintenance of cardiac function, including optimal digitalization. If hypotension occurs or congestive heart failure worsens, Norpace should be discontinued and, if necessary, restarted at a lower dosage only after adequate cardiac compensation has been established.**

QRS widening: **Although it is unusual, significant widening (greater than 25%) of the QRS complex may occur during Norpace administration; in such cases Norpace (disopyramide phosphate) should be discontinued.**

Q-T prolongation: **As with other Type 1 antiarrhythmic drugs, prolongation of the Q-T interval (corrected) and worsening of the arrhythmia may occur. Patients who have evidenced prolongation of the Q-T interval in response to quinidine may be at particular risk. If a Q-T prolongation of greater than 25% is observed and if ectopy continues, the patient should be monitored closely, and consideration be given to discontinuing Norpace (disopyramide phosphate).**

Hypoglycemia: **In rare instances significant lowering of blood glucose values has been reported during Norpace administration.** The physician should be alert to this possibility, especially in patients with congestive heart failure, chronic malnutrition, hepatic, renal or other diseases or drugs (e.g., beta adrenoceptor blockers, alcohol) which could compromise preservation of the normal glucoregulatory mechanisms in the absence of food. In these patients the blood glucose levels should be carefully followed.

Concomitant antiarrhythmic therapy: **The concomitant use of Norpace with other Type 1 antiarrhythmic agents (such as quinidine or procainamide) and/or propranolol should be reserved for patients with life-threatening arrhythmias who are demonstrably unresponsive to single agent antiarrhythmic therapy. Such use may produce serious negative inotropic effects, or may excessively prolong conduction.** This should be considered particularly in patients with any degree of cardiac decompensation or those with a prior history thereof. Patients receiving more than one antiarrhythmic drug must be carefully monitored.

Heart block: **If first-degree heart block develops in a patient receiving Norpace, the dosage should be reduced.** If the block persists despite reduction of dosage, continuation of the drug must depend upon weighing the benefit being obtained against the risk of higher degrees of heart block. Development of second- or third-degree AV block or unifascicular, bifascicular or trifascicular block requires discontinuation of Norpace therapy, unless the ventricular rate is adequately controlled by a temporary or implanted ventricular pacemaker.

Anticholinergic activity: **Because of its anticholinergic activity, Norpace should not be used in patients with glaucoma, myasthenia gravis or urinary retention unless adequate overriding measures are taken;** these consist of the topical application of potent miotics (e.g., pilocarpine) for patients with glaucoma, and catheter drainage or operative relief for patients with urinary retention. Urinary retention may occur in patients of either sex as a consequence of Norpace administration, but males with benign prostatic hypertrophy are at particular risk. In patients with a family history of glaucoma, intraocular pressure should be measured before initiating Norpace therapy. Norpace should be used with special care in patients with myasthenia gravis since its anticholinergic properties could precipitate a myasthenic crisis in such patients.

PRECAUTIONS

Atrial tachyarrhythmias: Patients with atrial flutter or fibrillation should be digitalized prior to Norpace administration to ensure that drug-induced enhancement of AV conduction does not result in an increase of ventricular rate beyond physiologically acceptable limits.

Conduction abnormalities: Care should be taken when prescribing Norpace for patients with sick sinus syndrome (bradycardia-tachycardia syndrome), Wolff-Parkinson-White syndrome (WPW), or bundle branch block. The effect of Norpace (disopyramide phosphate) in these conditions is uncertain at present.

Cardiomyopathy: Patients with myocarditis or other cardiomyopathy may develop significant hypotension in response to the usual dosage of Norpace, probably due to cardiodepressant mechanisms. Therefore, a loading dose of Norpace should not be given to such patients and initial dosage and subsequent dosage adjustments should be made under close supervision (see *Dosage and Administration*).

Drug interactions: Other antiarrhythmic drugs (e.g., quinidine, procainamide, lidocaine, propranolol) have occasionally been used concurrently with Norpace but no specific drug interaction studies have been conducted (see *Warnings*). Excessive widening of the QRS complex and/or prolongation of the Q-T interval may occur in these situations. Norpace does not increase serum digoxin levels.

Renal impairment: More than 50% of disopyramide is excreted in the urine unchanged. Therefore Norpace dosage should be reduced in patients with impaired renal function (see *Dosage and Administration*). The electrocardiogram should be carefully monitored for prolongation of PR interval, evidence of QRS widening or other signs of overdosage (see *Overdosage*).

Hepatic impairment: Hepatic impairment also causes an increase in the plasma half-life of disopyramide. Dosage should be reduced for patients with such impairment. The electrocardiogram should be carefully monitored for signs of overdosage (see *Overdosage*).

Hypokalemia: Antiarrhythmic drugs may be ineffective in patients with hypokalemia. Therefore, any potassium deficit should be corrected before instituting Norpace (disopyramide phosphate) therapy.

Pregnancy: Reproduction studies in rats and teratology studies performed both in rats and in rabbits have revealed minimal evidence of impaired fertility. No fetal anomalies were attributable to Norpace. Disopyramide has been found in human fetal blood. However, well-controlled studies of Norpace have not been performed in pregnant women and experience with Norpace during pregnancy is limited; therefore the possibility of damage to the fetus cannot be excluded.

Norpace has been reported to stimulate contractions of the pregnant uterus. Norpace (disopyramide phosphate) should be used in pregnant women only when it is clearly indicated and the benefit/risk ratio has been carefully evaluated.

Labor and delivery: It is not known whether the use of Norpace during labor or delivery has immediate or delayed adverse effects on the fetus, or whether it prolongs the duration of labor or increases the need for forceps delivery or other obstetric intervention.

Nursing mothers: Studies in rats have shown that the concentration of disopyramide and its metabolites is between one and three times greater in milk than it is in plasma. Following oral administration, disopyramide has been detected in human milk at a concentration not exceeding that in plasma. Therefore, if use of the drug is deemed essential, an alternative method of infant feeding should be instituted.

Pediatrics: The safety and effectiveness of Norpace in children have not been established.

ADVERSE REACTIONS

The adverse reactions which were reported in clinical trials encompass observations in 1,500 patients, including 90 patients studied for at least four years. The most serious adverse reactions are hypotension and congestive heart failure. The most common adverse reactions, which are dose dependent, are associated with the anticholinergic properties of the drug. These may be transitory, but may be persistent or can be severe. Urinary retention is the most serious anticholinergic effect.

The following reactions were reported in 10-40% of patients:

Anticholinergic: dry mouth (32%), urinary hesitancy (14%), constipation (11%)

The following reactions were reported in 3-9% of patients:

Anticholinergic: blurred vision, dry nose/eyes/throat
Genitourinary: urinary frequency and urgency
Gastrointestinal: nausea, pain/bloating/gas
General: dizziness, general fatigue/muscle weakness, headache, malaise, aches/pains

The following reactions were reported in 1-3% of patients:

Anticholinergic: urinary retention
Genitourinary: impotence
Cardiovascular: hypotension with or without congestive heart failure, increased congestive heart failure (see *Warnings*), cardiac conduction disturbances (see *Warnings*), edema/weight gain, shortness of breath, syncope, chest pain
Gastrointestinal: anorexia, diarrhea, vomiting
Dermatologic: generalized rash/dermatoses, itching
Central nervous system: nervousness
Other: hypokalemia, elevated cholesterol/triglycerides

The following reactions were reported in less than 1%:

Depression, insomnia; dysuria; numbness/tingling; elevated liver enzymes; AV block; elevated BUN; elevated creatinine; decreased hemoglobin/hematocrit

Hypoglycemia has been reported in association with Norpace (disopyramide phosphate) administration (see *Warnings*).

Rarely, acute psychosis has been reported following Norpace therapy, with prompt return to normal mental status when therapy was stopped. Infrequent occurrences of reversible cholestatic jaundice have been reported in association with disopyramide therapy as have rare instances of reversible agranulocytosis. The physician should be aware of these possible reactions and should discontinue Norpace therapy promptly if they occur.

DOSAGE AND ADMINISTRATION

The dosage of Norpace (disopyramide phosphate) must be individualized for each patient on the basis of response and tolerance. The usual adult dosage of Norpace is 400 to 800 mg per day given in divided doses four times daily. The recommended dosage schedule for most adults is 150 mg every six hours. For patients whose body weight is less than 110 pounds (50 kg), the recommended dosage is 100 mg every six hours.

For patients with cardiomyopathy or possible cardiac decompensation, a loading dose, as discussed below, should not be given and initial dosage should be limited to 100 mg of Norpace every six hours. Subsequent dosage adjustments should be made gradually, with close monitoring for the possible development of hypotension and/or congestive heart failure (see *Warnings*).

For patients with moderate renal insufficiency (creatinine clearance greater than 40 ml/min) or hepatic insufficiency, Norpace dosage of 100 mg every six hours is recommended, with or without an initial loading dose of 200 mg.

For patients with severe renal insufficiency (C_{Cr} less than 40 ml/min) the recommended dosage regimen is an initial loading dose of 150 mg followed by a maintenance dose of 100 mg at intervals shown in the table below:

NORPACE DOSAGE INTERVAL FOR PATIENTS WITH RENAL INSUFFICIENCY

Creatinine clearance (ml/min)	40-30	30-15	less than 15
Approximate maintenance-dosing interval	q 8 hr	q 12 hr	q 24 hr

For patients in whom rapid control of ventricular arrhythmia is essential, an initial loading dose of 300 mg of Norpace (200 mg for patients whose body weight is less than 110 pounds) is recommended, followed by the appropriate maintenance dosage. Therapeutic effects are usually attained 30 minutes to three hours after administration of a 300-mg loading dose. If there is no response nor evidence of toxicity within six hours of the loading dose, 200 mg every six hours may be prescribed instead of the usual 150 mg. If there is no response to this dosage within 48 hours, either Norpace should then be discontinued or the physician should consider hospitalizing the patient for careful monitoring while subsequent doses of 250 or 300 mg every six hours are given. A limited number of patients with severe refractory ventricular tachycardia have tolerated daily doses of Norpace up to 1600 mg per day (400 mg every 6 hours) resulting in disopyramide plasma levels up to 9 mcg/ml. If such treatment is warranted, it is essential that patients be hospitalized for close evaluation and continuous monitoring.

Transferring to Norpace: The following dosage schedule based on theoretical considerations rather than experimental data is suggested for transferring patients with normal renal function from either quinidine sulfate or procainamide therapy (Type 1 antiarrhythmic agents) to Norpace therapy.

Norpace may be started using the regular maintenance schedule **without a loading dose** 6-12 hours after the last dose of quinidine sulfate or 3-6 hours after the last dose of procainamide.

In patients where withdrawal of quinidine sulfate or procainamide is likely to produce life-threatening arrhythmias, the physician should consider hospitalization of the patient.

OVERDOSAGE

No specific antidote for Norpace has been identified. Treatment of overdosage should be supportive and may include the administration of isoproterenol, dopamine, hemoperfusion with charcoal, hemodialysis, intra-aortic balloon counterpulsation and mechanically assisted respiration.

In vitro studies with human blood have demonstrated good dialyzability for disopyramide. Its clearance was 33 ml/min at a blood flow of 250 ml/min when an initial plasma concentration of 22 mcg/ml was dialyzed using an artificial kidney (Cordis-DOW-4).

On the basis of animal studies toxic plasma levels of disopyramide might be expected to produce excessive widening of the QRS complex and Q-T interval, worsening of congestive heart failure, hypotension, varying kinds and degrees of conduction disturbance, bradycardia and finally asystole. Obvious anticholinergic effects might also be observed. The electrocardiogram should be monitored and supportive therapy with vasopressors, sympathomimetics, cardiac glycosides and diuretics should be given as required.

HOW SUPPLIED

Norpace (disopyramide phosphate) is supplied in hard gelatin capsules containing either 100 mg or 150 mg of disopyramide base.

Norpace 100-mg capsules are white and orange, with markings SEARLE and 2752. Norpace 150-mg capsules are brown and orange, with markings SEARLE and 2762.

Available in bottles of 100, 500, and 1,000 capsules, and cartons of 100 unit-dose individually blister-sealed capsules.

Adrenergic Regulation of Total Systemic Distensibility

Venous Distensibility Effects of Norepinephrine and Isoproterenol Before and After Selective Adrenergic Blockade

DAVID L. RUTLEN, MD*
EDWARD W. SUPPLE, MD
WILLIAM JOHN POWELL, Jr., MD, FACC

Boston, Massachusetts

The extracardiac factors that influence cardiac performance are arterial pressure and the venous return of blood to the heart. Venous return is influenced by the capacity and the distensibility characteristics of the peripheral capacitance vasculature. Distensibility determines the extent to which venous pressure increases and hence the extent to which venous return and cardiac performance increase when volume is added rapidly to the intravascular space. Thus an understanding of vascular distensibility is important to an understanding of integrated cardiovascular function. Because the influence of selective alpha and beta adrenergic receptor stimulation on total vascular distensibility is not well understood, the present study was undertaken to examine the distensibility effects of norepinephrine and isoproterenol before and after selective adrenergic receptor blockade. Fifty-one dogs were anesthetized, subjected to ganglionic block and placed on cardiopulmonary bypass at 1.5 liters/min. The reciprocal of distensibility or compliance was determined by sudden, transient occlusion of venous return and observation of the increase in central venous pressure (CVP) after a given amount of blood volume was added to the circulation (ΔCVP/83 ml). Norepinephrine, 30 μg/min, and isoproterenol, 6 μg/min, were each infused for 24 minutes. Norepinephrine was associated with an initial, transient (2 minute) increase in ΔCVP/83 ml of 18 $\pm$ 3 percent (mean $\pm$ standard error of the mean) ($p < 0.001$) above a control level of 16.9 $\pm$ 0.9 cm H_2O/83 ml, followed by a sustained decrease of 7 $\pm$ 3 percent ($p < 0.05$) below control level. Isoproterenol was associated with a decrease, which was both initial and sustained, in ΔCVP/83 ml of 19 $\pm$ 3 percent ($p < 0.001$) below a control level of 17.5 $\pm$ 1.0 cm H_2O/83 ml.

Selective blockade with phenoxybenzamine and propranolol revealed that the norepinephrine effect was mediated almost entirely through alpha adrenergic receptor stimulation and the isoproterenol effect mostly through beta adrenergic stimulation. Thus alpha and beta adrenergic receptor stimulation with norepinephrine and isoproterenol, respectively, is associated with sustained increases in total systemic vascular distensibility and would be expected to be associated with diminished increases in venous pressure, venous return and cardiac performance when a given amount of volume is added to the intravascular space.

Cardiac performance is dependent on both systemic arterial resistance and venous return.[1] Venous return by means of the Frank-Starling mechanism is a major, if not the major, determinant of cardiac performance.[2–4] Venous return is dependent on both peripheral vascular capacity and the compliance or distensibility characteristics of the peripheral venous circulation. Changes in systemic vascular capacity result in translocations of intravascular volume between the central (heart and lungs) and peripheral circulations. Distensibility is related to the extent by which venous pressure is altered and subsequently venous return and

cardiac output are altered when volume is added to or removed from the venous circulation. For example, if volume is added to the venous circulation at a given venous pressure and capacity, venous vascular distensibility determines the extent by which venous pressure increases. The extent by which venous pressure increases determines the magnitude of the increase in venous return. The magnitude of the increment in venous return, through the Frank-Starling mechanism, determines the extent by which cardiac performance is increased. Thus the distensibility of the venous circulation is a very important factor in overall circulatory function during intravenous volume repletion.

Little is known about the effects of adrenergic agents on total venous distensibility. Alexander[5] examined the effects of phenylephrine and epinephrine in an isolated mesenteric vein preparation. He found that at higher venous distending pressures, the administration of either of these agents was associated with an increase in venous distensibility. At lower distending pressures, he noted no change in distensibility. Ross et al.[6] assessed the effects of norepinephrine and epinephrine on venous distensibility in the total animal. They found that norepinephrine and epinephrine were both associated with increases in vascular distensibility at a single control level of venous pressure. However, they did not assess the possibility that the level of central venous pressure might modulate the effect of catecholamines on total vascular distensibility, as suggested by the work of Alexander. Furthermore, neither study examined the effect of selective alpha or beta adrenergic receptor stimulation on total venous distensibility. It is important for the clinician to have a basic understanding of the selective effects of alpha and beta adrenergic receptor stimulation on venous distensibility when a sympathomimetic drug is selected for therapeutic intervention. For example, if alpha or beta adrenergic receptor stimulation increases vascular distensibility, it would be expected that venous pressure and venous return would increase less with intravenous volume repletion in the presence of an alpha or beta adrenergic agent than if that agent were absent.

Thus the present study assessed the effects of alpha and beta adrenergic receptor stimulation on total systemic distensibility by employing norepinephrine and isoproterenol, two commonly utilized clinical agents, both before and after selective adrenergic receptor blockade. The effects of these agents on distensibility over a range of central venous pressures were examined. The model employed was a canine cardiopulmonary bypass preparation in which a change in pressure in the systemic venous vasculature could be determined as a function of the volume added to the systemic vasculature.

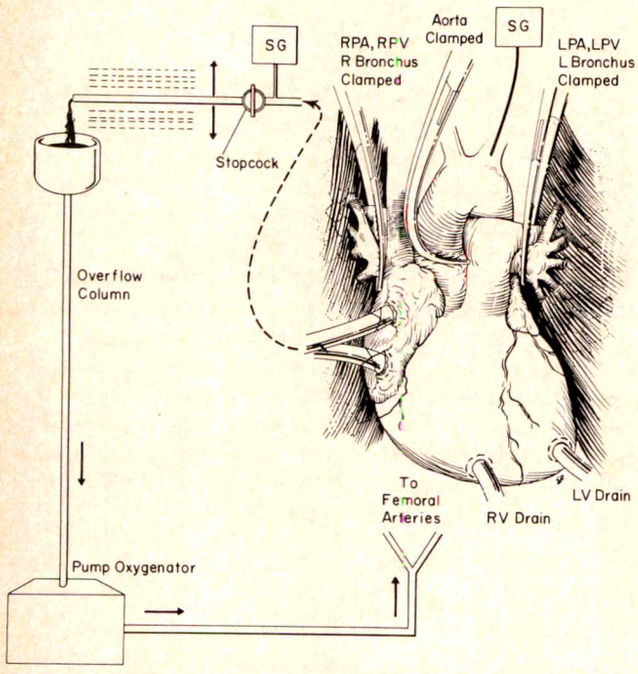

FIGURE 1. Experimental preparation. Dogs were placed on total cardiopulmonary bypass. Intermittent venous occlusions were accomplished by turning the stopcock. See text for details. LPA = left pulmonary artery; LPV = left pulmonary vein; LV = left ventricle; RPA = right pulmonary artery; RPV = right pulmonary vein; RV = right ventricle; SG = strain gauge.

Methods

Experimental Preparation (Fig. 1)

Fifty-one dogs weighing 17 to 25 kg were anesthetized with chloralose (60 mg/kg intravenously) and urethane (600 mg/kg intravenously). After tracheal intubation, respiration was achieved with a Harvard respirator using 97 percent oxygen/3 percent carbon dioxide. A median sternotomy was performed and 3 mg/kg of heparin was administered intravenously. The azygos vein was ligated. Total venous return to the reservoir of a pump oxygenator was accomplished by cannulating the superior and inferior venae cavae through the right atrial appendage with Argyle 32 French catheters. A 90° rotation of a stopcock (internal diameter 12 mm) produced rapid and complete occlusion of the systemic venous drainage tubing (internal diameter 13 mm). Central venous pressure was measured in the venous return line between the stopcock and the animal and was set at a predetermined level by adjusting the height of a venous overflow column. The roller pump (Cardiovascular Instruments, Wakefield, Massachusetts), returning oxygenated blood to the femoral arteries of the dog, was set at 1.5 liters/min. Blood was oxygenated using a Harvey model H-1000 oxygenator (William Harvey, Santa Ana, California). Arterial pressure was measured through a cannula in the subclavian artery. The aorta was cross-clamped 2 cm above the aortic valve, and the pulmonary hila were clamped to exclude the coronary, pulmonary and bronchial circulation. Hence any contribution of the cardiac chambers or pulmonary vasculature to total systemic compliance was excluded. The adequacy of clamping was demonstrated by the absence of flow from drains placed in both ventricles. All pressures were monitored using Statham

P23Db pressure transducers; the frequency response of the pressure measurement system was linear up to 30 cycles/s. Pressures were recorded on a Hewlett-Packard model 7700 eight-channel recorder at a paper speed of 25 mm/s.

Assessment of systemic distensibility and compliance: In order to assess total systemic distensibility or compliance, the stopcock was rapidly turned to the closed position, and central venous pressure was allowed to increase for more than 3.3 seconds. The stopcock was then rapidly turned to the open position, and central venous pressure promptly decreased toward its preocclusion level. Because the output of the roller pump was constant, the volume of blood pumped per unit of time was known. Hence it was possible to ascertain the change in pressure per unit of volume pumped into the systemic vasculature, that is, the inverse of distensibility or compliance. We recognize that the total systemic capacitance vasculature is composed of several separate components arranged in parallel.[7–10] Distensibility in any one of these components may be altered passively by changes in resistance to inflow to that component or by active vasoconstriction or dilation in that component. The present model allows an assessment of overall vascular distensibility in all components of the capacitance vasculature.

In preliminary studies we observed that with different interventions, the initial rate of increase of central venous pressure as a function of volume pumped was proportional to the change in pressure several seconds after occlusion. It was found that the appropriate time to measure the change in central venous pressure at a perfusion rate of 1.5 liters/min was 3.3 seconds after venous occlusion when 83 ml had been pumped (Fig. 2). At this point changes in the increase in central venous pressure produced by drug infusion could easily be noted, and at this time pressure never exceeded 35 mm Hg. It might be argued that 3.3 seconds is an insufficient period for venous pressure to be transmitted in retrograde fashion to the small veins and postcapillary venules where the major portion of the intravascular volume is located. Thus, measuring the change in central venous pressure after such a relatively brief period might not allow an adequate assessment of compliance. However, a pressure increment has been transmitted in retrograde manner to such an extent by 3.3 seconds that arterial pressure has increased slightly (Fig. 2). Thus, the change in venous pressure when 83 ml of infusate has been pumped (ΔCVP/83 ml) is a reasonable assessment of total systemic distensibility.

Ganglionic blockade was produced by the administration of 100 mg of mecamylamine (Inversine®, Merck, Sharpe & Dohme, West Point, Pennsylvania) to the pump reservoir over 10 minutes. This dose was adequate to abolish entirely 50 mm Hg increases in perfusion pressure obtained by clamping a single carotid artery below the bifurcation in preliminary experiments. Bilateral cervical vagectomy was also performed.

Adrenergic Receptor Regulation

Isoproterenol (Isuprel®, Winthrop Laboratories, New York, New York), 6 μg/min, norepinephrine (Levophed®, Winthrop Laboratories), 30 μg/min and methoxamine (Vasoxyl®, Burroughs Wellcome Co., Research Triangle Park, North Carolina), 200 or 400 μg/min, were each infused with a parenteral Fluid Delivery System (IV 5000, Valleylab, Boulder, Colorado). Each drug was dissolved in normal saline solution at concentrations that allowed infusion of the solutions at 2 ml/min. Alpha and beta adrenergic receptor blockade was achieved with phenoxybenzamine (Dibenzyline®, Smith, Kline & French Laboratories, Philadelphia, Pennsylvania), 0.1 to 2.0 g, and propranolol (Inderal®, Ayerst Laboratories, New York, New York), 20 to 200 mg, administered intravenously. Pharmacologic blockade was assessed by noting systemic arterial pressure responses to bolus injections of 300 μg of phenylephrine (Neosynephrine®, Winthrop Laboratories) and 12 μg of isoproterenol administered intraarterially before and after blockade. Arterial pressure responses with these agents were abolished before and after each experimental infusion administered in the presence of alpha or beta adrenergic blockade.

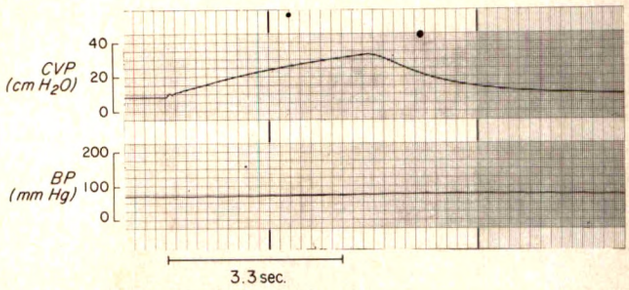

FIGURE 2. Representative tracing of central venous pressure (CVP) and arterial pressure (BP) before, during and after venous occlusion. Venous return to the reservoir was occluded at the beginning of the 3.3 second period. Central venous pressure after venous occlusion had not quite returned to the control level in this tracing, but it did so by 2 minutes.

Norepinephrine and isoproterenol infusions: In 31 animals, norepinephrine or isoproterenol, or both, was administered for 24 minutes. Venous occlusions were performed every 2 minutes during each infusion and during control periods before and after each infusion, except for the first 2 minutes of drug administration, when occlusions were performed every 30 seconds. The drugs were administered in a random fashion and were infused before and after selective alpha or beta adrenergic receptor blockade or double blockade. Normal saline solution alone was infused at 2 ml/min in four of these animals, and venous occlusions were performed before and during the infusion as described earlier. In two other animals, norepinephrine was infused at 3.75, 7.5 and 15 μg/min for 24 minutes but at concentrations that still allowed infusion rates of 2 ml/min. Splenectomy was performed in five other animals to eliminate the contractile effect of norepinephrine on the muscular capsule of the spleen.[11,12] In these animals, norepinephrine was infused on seven occasions at 30 μg/min for 24 minutes. In two other animals

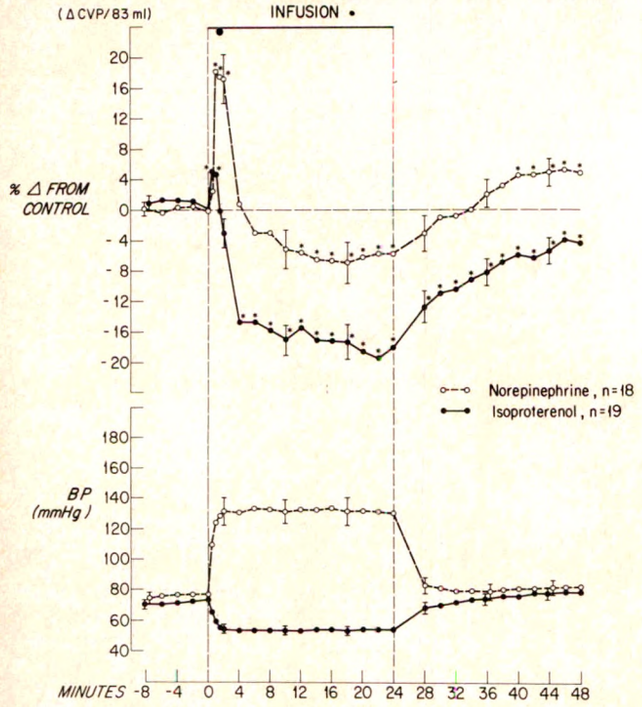

FIGURE 3. Change in central venous pressure (CVP) after 83 ml of infusate had been pumped (ΔCVP/83 ml) and arterial pressure (BP) during norepinephrine and isoproterenol infusion. Norepinephrine was infused at 30 μg/min and isoproterenol at 6 μg/min. Each **bar** represents ± 1 standard error of the mean. **Asterisks** indicate statistical significance ($p < 0.05$) compared with the preinfusion control values.

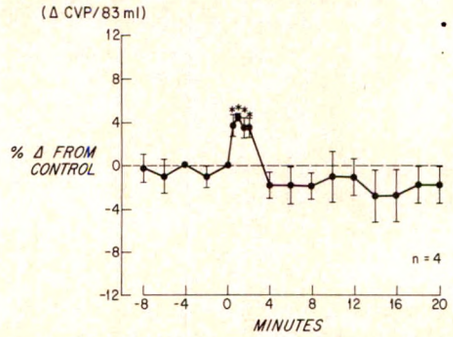

FIGURE 4. ΔCVP/83 ml during infusion of normal saline solution at 2 ml/min from time 0 to 20 minutes. Symbols and abbreviations as in Figure 3.

without splenectomy, methoxamine was infused on three occasions at 200 or 400 μg/min for 24 minutes.

In 11 animals, the effect of norepinephrine and isoproterenol infusions on the response to venous occlusion was assessed at central venous pressures of 3, 8 and 13 cm H_2O. In these experiments, venous occlusions were performed at these three venous pressures before each infusion of norepinephrine or isoproterenol, just before the termination of each infusion and at 10 minute intervals for 30 minutes after each infusion. At least 2 minutes of equilibration was allowed whenever venous pressure was altered. Central venous pressure was maintained at 3 cm H_2O between each set of venous occlusions. In these experiments norepinephrine and isoproterenol were administered for 15 and 10 minutes, respectively.

Statistical analysis: For each infusion, the percent change from the value of the ΔCVP/83 ml immediately before drug administration was determined for each value of ΔCVP/83 ml. Means were computed for the percent changes at each point in time for all experiments in each experimental group. A double-tailed Student's *t* test was then performed on all means in each group to ascertain whether the changes were statistically significant. Significance was assumed only with probability (p) values less than 0.05.

Results

Effects of isoproterenol and norepinephrine infusion (Fig. 3): Isoproterenol was associated with a transient initial increase in central venous pressure when 83 ml of infusate had been pumped (ΔCVP/83 ml) of only 5 ± 1 percent (mean ± standard error of the mean) ($p < 0.001$) above a control level of 17.5 ± 1.0 cm H_2O/83 ml, which lasted only 1 minute from the onset of infusion; ΔCVP/83 ml then decreased. This decrease persisted for the duration of the infusion and reached a minimum of 19 ± 3 percent ($p < 0.001$) below control. Thus isoproterenol was associated with a sustained increase in distensibility.

Norepinephrine administration was associated with an initial increase in ΔCVP/83 ml of 18 ± 3 percent ($p < 0.001$) above a control level of 16.9 ± 0.9 cm H_2O/83 ml; ΔCVP/83 ml then decreased. This decrease persisted for the duration of the infusion and reached a minimum of 7 ± 3 percent ($p < 0.05$) below the control value. Thus, norepinephrine was associated with an initial decrease followed by a sustained increase in distensibility. During the last 8 minutes of the postnorepinephrine control period, ΔCVP/83 ml was significantly increased above the control level. In the nine animals in which norepinephrine was administered without a previous infusion of isoproterenol, the sustained decrease in ΔCVP/83 ml during norepinephrine was similar to that in Figure 3, and ΔCVP/83 ml returned to, but not above, control levels after termination of the infusion. Thus the mean increase in ΔCVP/83 ml during the postnorepinephrine period in Figure 3 was probably due to a persistent isoproterenol effect lowering ΔCVP/83 ml before norepinephrine infusion in the animals that received isoproterenol before norepinephrine. Note that arterial pressure rapidly increased to a peak and remained at that level for the duration of norepinephrine administration.

When venous occlusions were performed during infusion of normal saline solution at the same intervals as those in Figure 3, ΔCVP/83 ml increased significantly to 5 percent above the control value during the first 2 minutes of the infusions (Fig. 4). This increase during saline infusion was probably due to an inadequate period of time for blood to leave the capacitance vasculature between occlusions, which were performed every 30 seconds during the first 2 minutes of the infusions. Thus the initial increase in ΔCVP/83 ml with norepinephrine was more than could be accounted for by the

TABLE 1.

Compliance Changes With Small Dose Administration of Norepinephrine

	Control	2 min	4 min	8 min	24 min
3.75 μg/min of Norepinephrine					
ΔCVP/83 ml*	23 cm H_2O	+4%	−4%	−4%	−9%

* Animal 1. † Animal 2.

The control value for ΔCVP/83 ml is expressed as an absolute value. Subsequent values of ΔCVP/83 ml during each infusion are expressed as percent changes compared with the control value. BP = arterial pressure; CVP = central venous pressure.

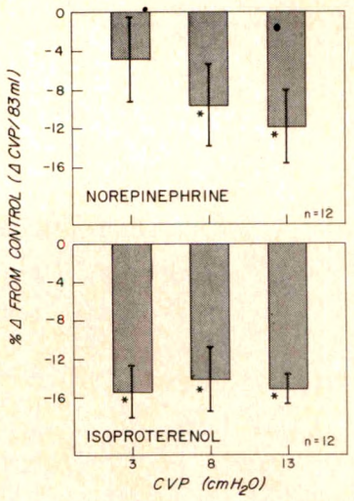

FIGURE 5. Effects of norepinephrine and isoproterenol on ΔCVP/83 ml at three levels of central venous pressure (CVP). Norepinephrine was infused for 15 minutes at 30 μg/min and isoproterenol for 10 minutes at 6 μg/min. Symbols and abbreviations as in Figure 3.

technique alone, whereas the initial increase with isoproterenol appeared secondary to the frequent clamping.

The hemodynamic changes associated with 24 minutes of norepinephrine infusion at concentrations less than 30 μg/min are shown in Table I. Note that except for the absence of an initial increase in ΔCVP/83 ml during some of the infusions, the changes are directionally similar to those in Figure 3.

In the five splenectomized animals, norepinephrine at a concentration of 30 μg/min was associated with an initial increase in ΔCVP/83 ml of 11 ± 3 percent ($p < 0.01$) above a control level of 21 ± 1 cm H_2O/83 ml. This initial increase was greater than that produced by the technique alone (Fig. 4). ΔCVP/83 ml subsequently decreased to 14 ± 2 percent ($p < 0.001$) below control after 24 minutes of norepinephrine infusion in these splenectomized animals.

Changes in venous distensibility (ΔCVP/83 ml) at various levels of central venous pressure (Fig. 5): The administration of norepinephrine did not produce a significant decrease in ΔCVP/83 ml at a central venous pressure of 3 cm H_2O. At this pressure, ΔCVP/83 ml was actually increased at the end of the 15 minute norepinephrine infusion on three occasions, unchanged on another three occasions and decreased at the end of the other six infusions. Norepinephrine administration at central venous pressures of 8 and 13 cm H_2O and isoproterenol administration at all three pressure levels examined revealed significant decreases in ΔCVP/83 ml at the end of the infusions. Control values of ΔCVP/83 ml were 9.9 ± 2.6, 10.5 ± 2.7 and 11.4 ± 2.9 cm H_2O/83 ml at central venous pressures of 3, 8 and 13 cm H_2O, respectively, for norepinephrine infusion and 11.2 ± 3.5, 10.7 ± 2.4 and 11.1 ± 2.4 cm H_2O/83 ml for isoproterenol infusion. The different durations of infusion for norepinephrine (15 minutes) and isoproterenol (10 minutes) were chosen because decreases in ΔCVP/83 ml had reached levels that were relatively stable and significantly below the control value by 15 minutes with norepinephrine and by 10 minutes with isoproterenol (Fig. 3). In two animals in which norepinephrine and isoproterenol were each infused twice at a central venous pressure of 8 cm H_2O, no attenuation of the changes in ΔCVP/83 ml occurred during the second infusion of each drug.

Effects of alpha and beta adrenergic receptor blockade with phenoxybenzamine or propranolol: The effects of norepinephrine after administration of either 100 mg of phenoxybenzamine or 20 mg of propranolol were studied (Fig. 6). After 20 mg of propranolol, the sustained decrease in ΔCVP/83 ml was minimally but not significantly attenuated. After 100 mg of phenoxybenzamine alone, the initial increase in ΔCVP/83 ml was the same as without alpha adrenergic receptor blockade, but the sustained decrease in ΔCVP/83 ml was abolished. In these experiments with norepinephrine administration after 100 mg of phenoxybenzamine, the initial increase in ΔCVP/83 ml was associated with a small and transient but steep increase in arterial pressure, suggesting the possibility that alpha adrenergic blockade was not complete. In two other animals, alpha adrenergic receptor blockade with a larger dose of phenoxybenzamine (2 g) abolished both the norepinephrine-associated initial increase and the subsequent sustained decrease in ΔCVP/83 ml.

Whenever norepinephrine was infused, there was an initial steep increase followed by a plateau or slight

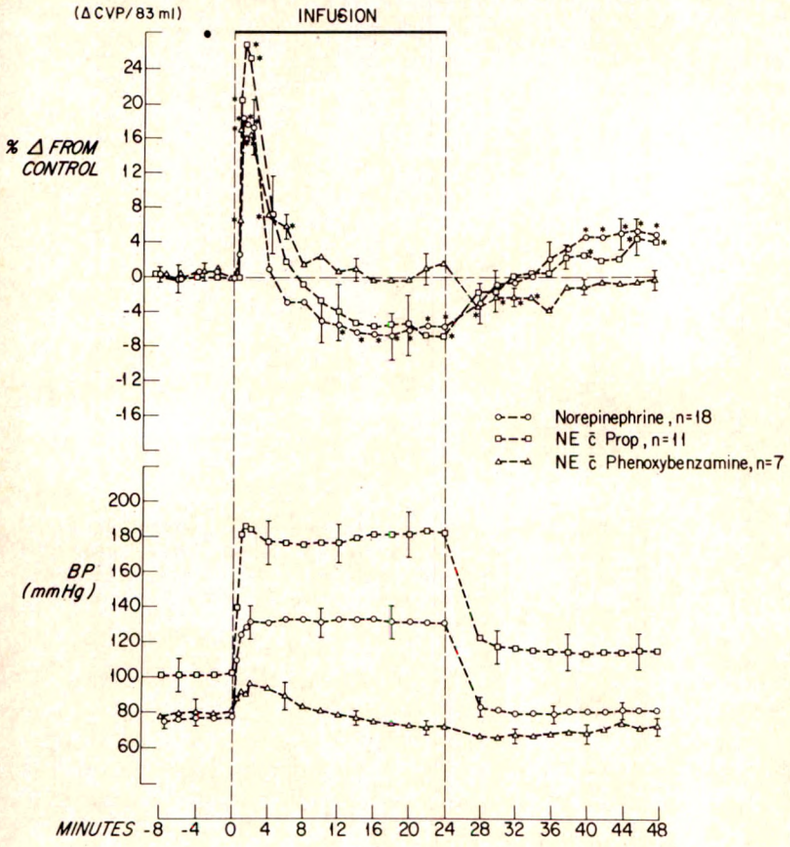

FIGURE 6. Effect of norepinephrine, 30 μg/min, without adrenergic blockade, and after blockade with either 20 mg of propranolol or 100 mg of phenoxybenzamine. The data associated with administration of norepinephrine (NE) in the absence of adrenergic blockade are reproduced from Figure 3. Note that the norepinephrine-associated decrease in ΔCVP/83 ml was abolished after alpha adrenergic blockade and was slightly but not significantly attenuated after beta adrenergic blockade. Control ΔCVP/83 ml was 16.9 ± 0.9 cm H_2O/83 ml before blockade, 17.9 ± 1.3 after alpha adrenergic blockade and 21.0 ± 1.2 after beta adrenergic blockade. Symbols and abbreviations as in Figure 3.

decrease in blood pressure. This initial increase in blood pressure was always associated with a transient increase in ΔCVP/83 ml. This association suggested the possibility that a progressive vasoconstrictor effect, albeit transient in these experiments, is associated with an increase in ΔCVP/83 ml. In this regard it was noted that when methoxamine was infused there was a progressive increase in arterial pressure (Fig. 7) throughout the duration of the the infusion (three infusions in two animals). In these experiments, ΔCVP/83 ml did not decrease below the control level and actually increased progressively in two infusions (Fig. 7).

The isoproterenol-associated decrease in ΔCVP/83 ml was attenuated after individual blockade with either 20 mg of propranolol or 100 mg of phenoxybenzamine (Fig. 8). After double blockade with these doses of both of the blocking agents, ΔCVP/83 ml still decreased slightly, although not significantly. Phenoxybenzamine (1 g) produced no further attenuation of the isoproterenol-associated decrease in ΔCVP/83 ml than had 100 mg phenoxybenzamine (Fig. 9). Subsequent double blockade with large dose propranolol (200 mg) and 1 g of phenoxybenzamine abolished the decrease in ΔCVP/83 ml. Beta adrenergic receptor blockade alone with larger dose (200 mg) propranolol almost but not entirely abolished the isoproterenol-associated decrease in ΔCVP/83 ml (Fig. 10). Subsequent double blockade by the addition of 1 g of phenoxybenzamine entirely abolished the decrease. In two animals, 300 μg of phenylephrine administered intraarterially was associated with respective increases in arterial pressure of 32 and 29 mm Hg before 200 mg of propranolol and increases of 33 and 30 mm Hg after 200 mg of propranolol. Thus it is unlikely that this dose of propranolol produced any alpha adrenergic receptor blockade.

Discussion

Effects of alpha and beta adrenergic stimulation on vascular capacity and distensibility: The present study demonstrates the influence of norepinephrine and isoproterenol on the distensibility or compliance characteristics of the peripheral capacitance vasculature. The data indicate that the administration of both norepinephrine and isoproterenol results in sustained increases in vascular distensibility; that is, when a given amount of volume is added to the circulation, venous pressure will increase less in the presence of either of these agents than in its absence. The data also demonstrate that the distensibility effects of norepinephrine and isoproterenol are mediated through alpha and beta adrenergic receptor stimulation, respectively.

It must be remembered that alpha and beta adrenergic receptor stimulation affects both vascular capacity and vascular distensibility. Previous work has demonstrated that such stimulation decreases total systemic vascular capacity.[13,14] This change in capacity occurs relatively rapidly (10 to 15 minutes) and is associated with a new steady state peripheral systemic

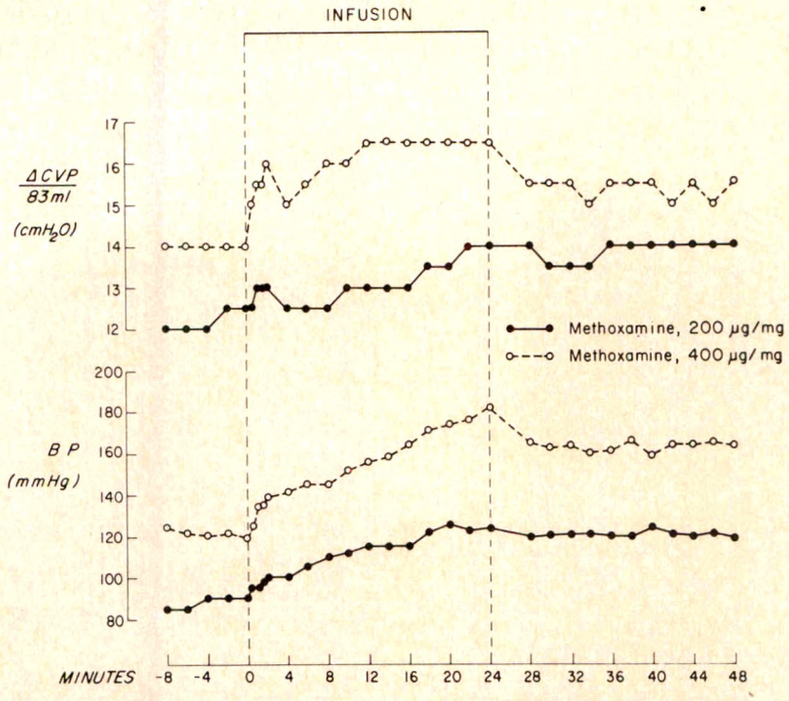

FIGURE 7. ΔCVP/83 ml and arterial pressure during infusions of methoxamine at two different doses. Small dose methoxamine was infused first. Note that arterial pressure continued to increase and ΔCVP/83 ml remained increased above control for the duration of each infusion. ΔCVP/83 ml is expressed as an absolute value. Abbreviations as in Figure 3.

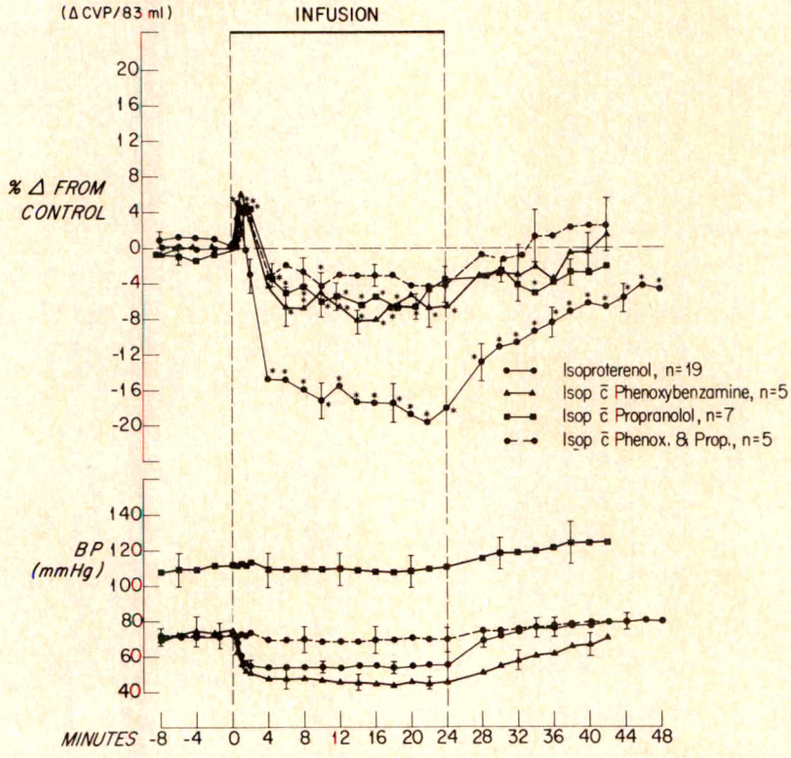

FIGURE 8. Effect of isoproterenol (Isop), 6 μg/min, without adrenergic blockade and after blockade with either 20 mg of propranolol (Prop.) or 100 mg of phenoxybenzamine (Phenox.) or after double blockade with both agents. The data associated with isoproterenol administration in the absence of adrenergic blockade are reproduced from Figure 3. Note that the isoproterenol-associated decrease in ΔCVP/83 ml was attenuated after either alpha or beta adrenergic blockade. After subsequent double blockade, ΔCVP/83 ml decreased a small but not statistically significant amount. Control ΔCVP/83 ml was 17.5 ± 1.0 cm H_2O/83 ml before blockade, 16.8 ± 2.0 after alpha adrenergic blockade, 20.4 ± 1.6 after beta adrenergic blockade and 19.0 ± 1.3 after double blockade. Symbols and abbreviations as in Figure 3.

intravascular volume. Under these steady state conditions, the change in peripheral capacity due to selective adrenergic receptor stimulation has already been manifested, and subsequent influences of adrenergic receptor stimulation on the capacitance circulation will be manifested as changes in vascular distensibility. Specifically, the influences will be apparent in terms of the extent to which the change in venous pressure, with volume repletion or depletion, is altered. The present data demonstrate that alpha and beta adrenergic stimulation is associated with significant sustained increases in vascular distensibility. Thus, once systemic vascular capacity has decreased secondary to adrenergic receptor stimulation, changes in venous pressure, resulting from subsequent repletion or depletion of the intravascular space, would be much smaller in the presence of alpha or beta receptor stimulation. For that reason, changes in venous return and cardiac output, after altering intravascular volume, would be attenuated during such stimulation.

Effects of norepinephrine: Norepinephrine administration is associated with an initial decrease in

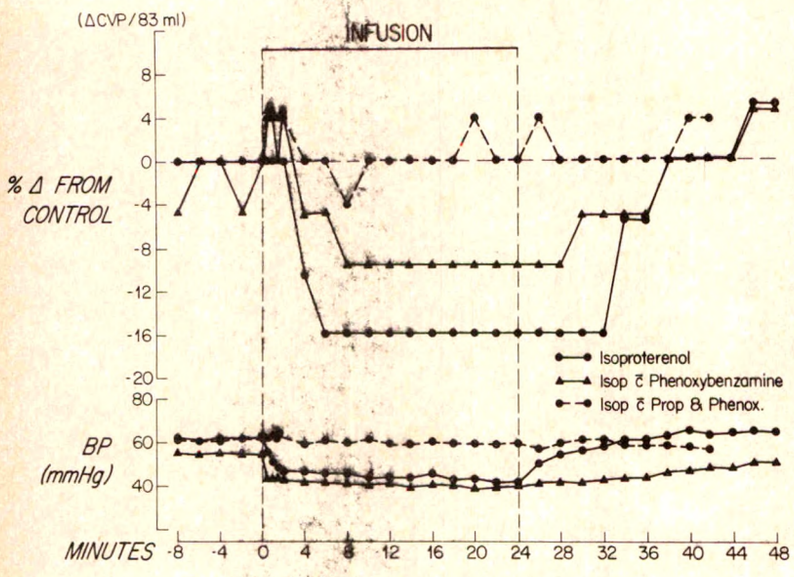

FIGURE 9. Effect of isoproterenol (Isop), 6 μg/min, in a single animal before blockade, after 1 g of phenoxybenzamine (Phenox.) and after double blockade with the subsequent administration of 200 mg of propranolol (Prop). Note that the isoproterenol-associated decrease in ΔCVP/83 ml was attenuated approximately the same amount with 1 g of phenoxybenzamine as it had been with 100 mg of phenoxybenzamine (Fig. 8). Control ΔCVP/83 ml was 9.5 cm H_2O/83 ml before blockade, 10.5 after alpha adrenergic blockade and 12.5 after double blockade. Abbreviations as in Figure 3.

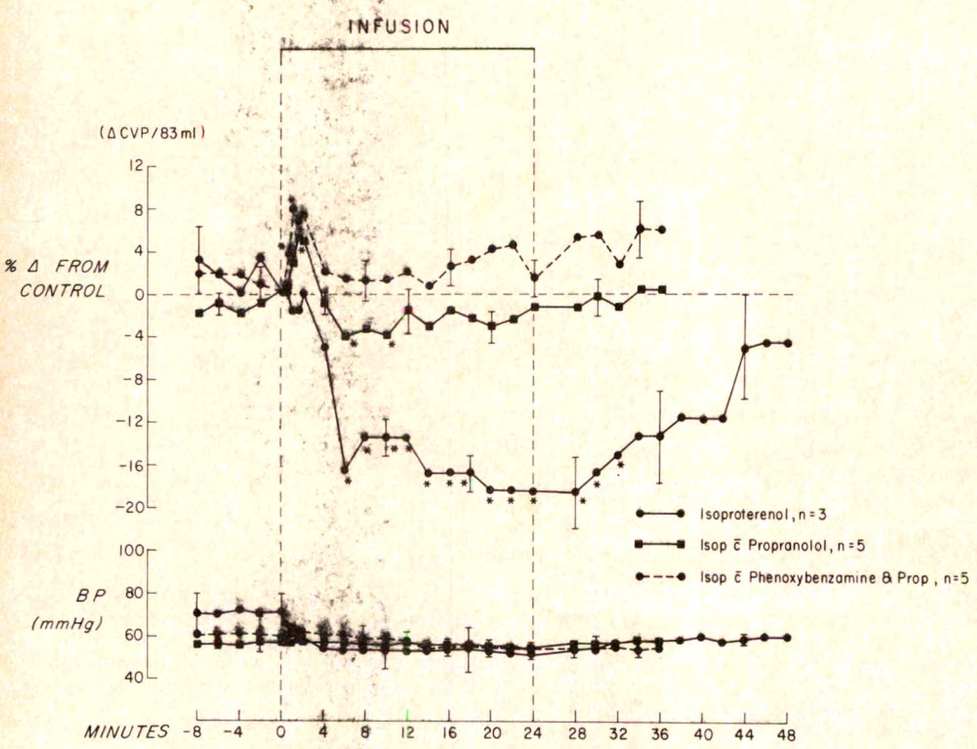

FIGURE 10. Effect of isoproterenol (Isop), 6 μg/min, before blockade, after 200 mg of propranolol (Prop) and after double blockade with the subsequent administration of 1 g of phenoxybenzamine. Note that the isoproterenol-associated decrease in ΔCVP/83 ml was almost but not entirely abolished after 200 mg of propranolol. With the subsequent addition of phenoxybenzamine, the isoproterenol-associated decrease in ΔCVP/83 ml was abolished. Control ΔCVP/83 ml was 10.0 ± 0.3 cm H_2O/83 ml before blockade, 10.3 ± 1.1 after beta adrenergic blockade and 10.6 ± 1.7 after double blockade. Symbols and abbreviations as in Figure 3.

total systemic distensibility. The decrease is mediated entirely through alpha adrenergic receptor stimulation as it is abolished after large dose alpha adrenergic blockade with phenoxybenzamine. It might be argued that the initial decrease in compliance with norepinephrine is due to a lower serum drug concentration during the initial period of infusion and the later sustained increase in distensibility is due to the subsequent development of a higher serum drug concentration. That this is not so is demonstrated by the lack of a prolonged decrease in distensibility even at lower levels of drug delivery (Table I). The initial decrease in distensibility may be related to the presence of progressive vasoconstriction because the decrease is manifest only while arterial pressure is increasing. In support of this argument is the observation that, for the duration of methoxamine administration, distensibility does not increase and either steadily decreases or remains constant while arterial pressure steadily increases. Thus it appears likely that progressively increasing alpha adrenergic receptor stimulation may be associated with a decrease in venous distensibility; that is, administration of a given amount of volume would result in a higher venous pressure during progressively increasing alpha adrenergic receptor stimulation than before stimulation.

However, once arterial pressure has stabilized with norepinephrine administration, systemic distensibility increases and eventually reaches a level significantly above the control value. Distensibility remains at this higher level for the duration of drug administration. This increase in distensibility with norepinephrine is mediated almost entirely through alpha adrenergic receptor stimulation, as the increase is abolished after pharmacologic blockade of alpha adrenergic receptors. It is possible that a small portion of the distensibility-increasing effect of norepinephrine is mediated through beta adrenergic receptor stimulation, because the increase in distensibility with norepinephrine is slightly but not significantly attenuated after beta adrenergic receptor blockade with propranolol. The importance of central venous pressure in modulating the influence of adrenergic agents on systemic distensibility is indicated by the observation that the sustained increase in distensibility with norepinephrine occurs only at higher central venous pressures. Neither the decrease nor the increase in distensibility associated with norepinephrine administration is mediated entirely through splenic constriction, as the bimodal pattern of response is still present in animals that have undergone splenectomy.

Effects of isoproterenol: Isoproterenol is associated with a marked increase in distensibility over a wide range of central venous pressures. This isoproterenol-associated increase appears predominantly related to beta adrenergic receptor stimulation, as the increase in distensibility is nearly eliminated after beta adrenergic receptor blockade with 200 mg of propranolol. It is unlikely that this dose of propranolol causes any substantial alpha adrenergic receptor blockade, because phenylephrine-associated increases in arterial pressure are not attenuated by this dose of propranolol. However, a small portion of the isoproterenol-associated increase in distensibility, is likely to be mediated through alpha adrenergic receptor stimulation for the following reasons: The isoproterenol effect on distensibility is present to a limited extent after blockade with 200 mg of propranolol alone, is entirely abolished after subsequent double blockade with propranolol and phenoxybenzamine, and is attenuated after blockade with 100 mg of phenoxybenzamine alone. The apparent attenuation by one half of the isoproterenol-associated increase in distensibility after 100 mg of phenoxybenzamine does not necessarily imply that isoproterenol exerts its effect to such a large extent through alpha adrenergic receptor stimulation. The attenuation may be related in part to shifts along the steady state pressure/volume curve caused by phenoxybenzamine. These shifts may affect the physical characteristics of the vasculature such that after phenoxybenzamine, the control level of distensibility does not change, but with subsequent isoproterenol administration, an apparent attenuation of the isoproterenol effect is manifest. Stimulation of both alpha and beta adrenergic receptors by isoproterenol is not totally unexpected, because recent in vitro studies suggest some affinity of isoproterenol for the alpha adrenergic receptor.[15]

Previous studies on vascular compliance or distensibility: Alexander,[5] employing an isolated mesenteric vein preparation, measured the increase in mesenteric vein pressure with volume infusion. He noted that phenylephrine administration was associated with an increase in compliance or distensibility at higher initial distending pressures but no change in compliance at lower distending pressures. In our study we noted sustained increases in total systemic compliance or distensibility with norepinephrine at central venous pressures of 8 and 13 cm H_2O but no significant change in total distensibility at a central venous pressure of 3 cm H_2O. Thus our results extend the observations of Alexander to the total systemic capacitance vasculature.

Ross et al.,[6] employing an animal preparation similar to ours, found that norepinephrine and epinephrine both produced increases in systemic compliance. However, norepinephrine and epinephrine are associated with both alpha and beta adrenergic stimulatory effects in the overall circulatory system. Because Ross et al. did not employ selective adrenergic receptor blockade, they could not ascertain whether the increases in compliance were due to alpha or beta adrenergic receptor stimulation or to both. Furthermore, they could not eliminate the possible contribution of peripheral or central baroreceptors to the catecholamine-associated effects, since they did not administer ganglionic blockade before catecholamine infusion as was done in our study.

Caldini et al.[7] and Mitzner and Goldberg[8] assessed intravascular compliance by noting changes in total intravascular volume associated with increments in right atrial pressure or changes in regional mean venous pressure associated with increments in regional intravascular volume. They found epinephrine to be associated with decreases in total and regional intravascular capacitance. However, they did not determine whether

the decrease in capacitance was due to alpha or beta adrenergic receptor stimulation, or both. It is possible that epinephrine produced progressive alpha adrenergic-mediated venoconstriction of the capacitance vasculature similar to that we observed during the initial period of norepinephrine infusion or throughout the period of methoxamine infusion. Furthermore, they did not eliminate the possible contribution of central or peripheral baroreceptors.

Clinical implications: In addition to a better understanding of overall circulatory function, this study contributes to our understanding of cardiocirculatory function associated with such pathophysiologic states as congestive heart failure and to our knowledge of the therapeutic implications of sympathomimetic drug administration. It is well known that sympathetic tone is increased in the presence of congestive heart failure.[16–19] This elevation might be beneficial to the patient in that venous pressure would be expected to be increased much less for a given increment in vascular volume. Such attenuation would tend to protect the patient from central volume overload, which could produce pulmonary edema or ascites. However, much more volume would have to be removed from the intravascular space in order to decrease ventricular filling pressures. Thus the treatment of pulmonary edema or ascites might become more difficult. Similarly, in the presence of sympathomimetic drug administration, more volume would have to be administered intravenously in order to increase venous return and cardiac output, and a greater amount of volume would have to be removed in order to lower venous pressure. Because our work has assessed the influences of selective alpha and beta adrenergic receptor stimulation, the study should allow prediction of the distensibility effects of many adrenergic agents. Under steady state conditions and in the absence of progressive vasoconstriction, alpha and beta adrenergic agents would both be expected to be associated with increases in vascular distensibility. However, agents with more alpha adrenergic effects would tend to have smaller distensibility effects at low central venous pressures.

Acknowledgment

We are grateful to Luis Geurrero and Michael Bissanti for their surgical assistance, to Mindy Horowitz for her help in preparing the manuscript and to John Newell for the statistical analyses. We thank Valleylab (Boulder, Colorado) for donating the Fluid Delivery System, Ayerst Laboratories (New York, New York) for supplying the propranolol and Smith, Kline & French Laboratories (Philadelphia, Pennsylvania) for supplying the phenoxybenzamine.

Production of a Critical Coronary Arterial Stenosis in Closed Chest Laboratory Animals

Description of a New Nonsurgical Method Based on Standard Cardiac Catheterization Techniques

HENRY GEWIRTZ, MD
ALBERT S. MOST, MD, FACC

Providence, Rhode Island

A nonsurgical method for producing a critical coronary arterial stenosis in a closed chest laboratory animal would enhance our ability to study the effects of reversible myocardial ischemia on many aspects of left ventricular function and also would facilitate experiments aimed at studying the effects of various interventions on regional myocardial blood flow distal to a severe stenosis. Accordingly, a new technique was developed for the production of a critical coronary arterial lesion in a closed chest laboratory animal. Under fluoroscopic control a small plastic truncated cone (5 mm long, outside diameter 3.5 mm tapering to 3.25 mm) with a narrow, central internal lumen (diameter 0.625 mm) was passed over a guide wire into the left anterior descending coronary artery of a closed chest, heparinized pig (n = 6). Regional myocardial blood flow (microsphere technique) distal to the artificial stenosis (distal zone) and in myocardium perfused by the circumflex coronary artery was determined under the following conditions: at rest (control I), at the 10th minute of atrial pacing (190 min^{-1}) and 10 to 15 minutes after discontinuation of pacing (control II). At rest, transmural blood flow distal to the stenosis (1.29 ± 0.32 ml/min per g, mean ± standard deviation) was almost identical to that in the circumflex zone (1.31 ± 0.31, r = 0.93, p <0.01). During atrial pacing transmural flow increased significantly (p <0.01 versus control) in the circumflex zone (1.73 ± 0.27) and then returned to control value (1.34 ± 0.38) after pacing was discontinued. In contrast, transmural flow in the distal zone (1.45 ± 0.40) failed to increase significantly with pacing. In addition, during atrial pacing the endocardial to epicardial blood flow ratio distal to the stenosis decreased from 0.99 ± 0.13 (control I) to 0.68 ± 0.14 (p <0.01), whereas it remained unchanged in the circumflex zone (1.1 ± 0.11 to 1.1 ± 0.08, difference not significant). Finally, the artificial intraluminal stenosis remained patent for the duration of the study (5.1 ± 0.05 hours) in all animals. Thus the intracoronary plastic stenosis is a promising new method for the production of a critical coronary arterial lesion in closed chest laboratory animals.

Although the effects of coronary arterial occlusion on myocardial blood flow and function have proved relatively easy to model, a critical stenosis with reversible myocardial ischemia has posed a more difficult problem for investigators. Available techniques[1–7] require thoracotomy with consequent alteration of normal pericardial physiology and potential disruption of coronary arterial and myocardial nerve supply. Furthermore, the method of creating such a stenosis commonly involves externally constricting the coronary artery until resting blood flow through the vessel is reduced.[8–10] Because most human beings with chronic ischemic heart disease have normal regional blood flow at rest,[11] this aspect of the method may be undesirable.

From the Department of Medicine (Division of Cardiology), Rhode Island Hospital and Brown University Program in Medicine, Providence, Rhode Island. Manuscript received June 30, 1980; revised manuscript received September 8, 1980, accepted October 24, 1980.

Accordingly, we developed a new technique for studying the effects of a severe coronary arterial stenosis on regional myocardial blood flow and left ventricular function. The technique consists of inserting an occlusive plastic truncated cone with a narrow central internal lumen directly into the animal's coronary artery. This can be accomplished rapidly in a closed chest animal using standard cardiac catheterization techniques. Regional blood flow (microsphere technique) in myocardium distal to the stenosis and in myocardium perfused by the circumflex coronary artery was determined at rest and during and after rapid atrial pacing in order to confirm that a critical stenosis had been produced by the device.

Methods

Description of the artificial stenosis: The artificial stenosis was custom-turned on a machinist's lathe from a stock cylinder (diameter 6.4 mm) of Delrin™ (DuPont), a firm; hard, radiolucent plastic material. The device has the shape of a truncated cone and is 5 mm long with an outer diameter tapering from 3.50 to 3.25 mm (Fig. 1, top). An internal lumen bored through the center of the device with a drill bit 0.625 mm in diameter permitted blood to flow through it. The small internal lumen caused an 82 percent reduction in the diameter of the vessel at the point where the artificial stenosis came to rest. To help prevent clotting, the stenosis was coated inside and out with benzalkonium chloride-heparin complex (North American Science Associates, Toledo, Ohio) before placement in the coronary artery. This was accomplished by simply dipping it in the solution for 10 to 15 seconds and then drying it in an oven at 45°C for 10 minutes. The stenosis was recoated with this solution before each use. The surface of the internal lumen was relatively smooth and free of major deformities, although a few rough spots were observed (Fig. 1, bottom).

Animal preparation: Six closed chest pigs (weight 47 to 60 kg) were studied as described later in order to confirm that the device produced a critical coronary stenosis. A double

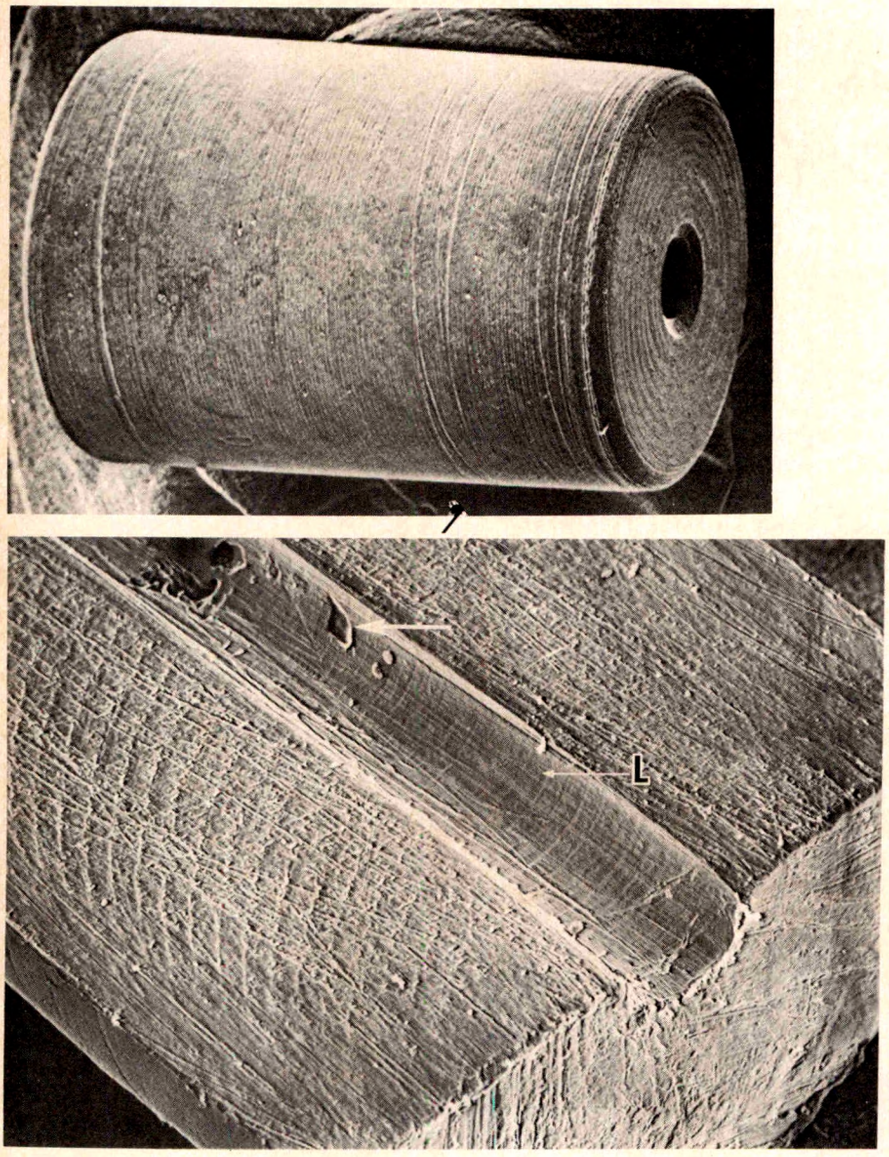

FIGURE 1. Scanning electron micrographs. **Top,** of an artificial stenosis. The external surface is relatively smooth although it is covered with innumerable tiny grooves. The grooves were caused by the machinist's tool as the device was turned on a lathe. The distal surface of the stenosis is visible **at right**. The proximal surface (not shown) appeared similar except for two very small burrs visible at the mouth of the internal lumen. **Bottom,** the surface of the internal lumen (L) of the artificial stenosis. The device has been cut in half along its long axis to permit examination of the lumen. The surface has several small gouges (**arrow**) at its distal end (**upper left**) as well as several ridges extending along its length. Otherwise it is relatively smooth and free of major deformities. (Magnification: **top** ×34, **bottom** ×43, both reduced by 34 percent.)

lumen 8 French catheter was placed in the thoracic aorta through the left femoral artery. The arterial catheter was used to monitor pressure and to obtain samples of blood for determination of pH and partial pressure of oxygen and carbon dioxide. Another cutdown was performed over the right femoral artery and vein. An 8 French angiographic catheter was advanced from the femoral artery under fluoroscopic guide and placed retrograde in the left atrium. The right femoral vein was used to advance another 8 French angiographic catheter into the main pulmonary artery. In addition, a 7 bipolar pacing catheter was placed in the coronary sinus through the right internal jugular vein. Pressure was monitored from all catheters with Statham P23db transducers and recorded on paper with a Hewlett-Packard 8 channel recorder (model 7788A). The left atrial catheter was used for injection of radiolabeled microspheres to determine regional myocardial blood flow.[12] The pulmonary arterial catheter was used for injection of indocyanine green to determine cardiac output by the dye-dilution technique (Cardiac Output Computer, model COCS, Lexington Instruments, Lexington, Massachusetts). After placement of the catheters the animal was systemically anticoagulated with heparin (225 IU/kg intravenously). Thereafter, half of the loading dose was given every hour for the remainder of the study.

An Amplatz catheter was inserted in the right carotid artery and advanced under fluoroscopic control to the origin of the left anterior descending coronary artery (Fig. 2). The artery was visualized by injection of 3 to 5 cc of Renografin,™ and its mid and distal points were marked on the video monitor. After that a Teflon®-coated guide wire with a diameter of 0.533 mm and a 3 cm floppy distal end (Cook Inc., Bloomington, Indiana) was advanced through the Amplatz catheter into the distal portion of the coronary artery. The Amplatz catheter then was removed, leaving only the guide wire within the artery. Next, the proximal end of the wire was inserted through the central lumen of the plastic stenosis. The device was then pushed along the wire and into the coronary artery by means of a 50 cm long, thin-walled flexible plastic catheter (inside diameter 0.76 mm, outside diameter 0.77 mm). Both the wire and "pushing" catheter were then quickly removed, leaving the artificial stenosis firmly in place within the lumen of the coronary artery (Fig. 3).

Experimental protocol: After the stenosis had been placed in the animal's coronary artery, cineangiography was performed with the animal in a 45° left anterior oblique position. This was done to document the location of the stenosis and to be sure that blood continued to flow through it. The angiogram was obtained with Kodak CFX 35 mm film after hand injection of 4 to 6 cc of Renografin. The film was exposed at 60 frames/s at a setting of 80 kV and 150 mA. A Philips 6 inch (152.4 mm) image intensifier with cesium iodide phosphor was

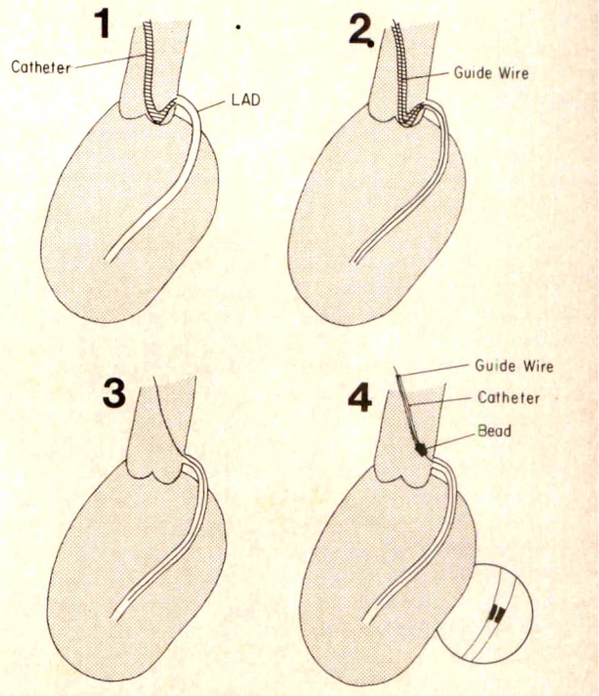

FIGURE 2. Diagram of the procedure for placement of the intracoronary plastic stenosis. Under fluoroscopic control an Amplatz catheter is placed at the origin of the left anterior descending (LAD) coronary artery (**1**). A guide wire (diameter 0.533 mm) is passed through the catheter into the artery (**2**), after which the catheter is removed, leaving the wire in place (**3**). The plastic stenosis is threaded over the wire and advanced into the coronary artery with the aid of a thin, flexible pushing catheter (**4**). The guide wire and pushing catheter are then removed, leaving the stenosis in place (**inset**).

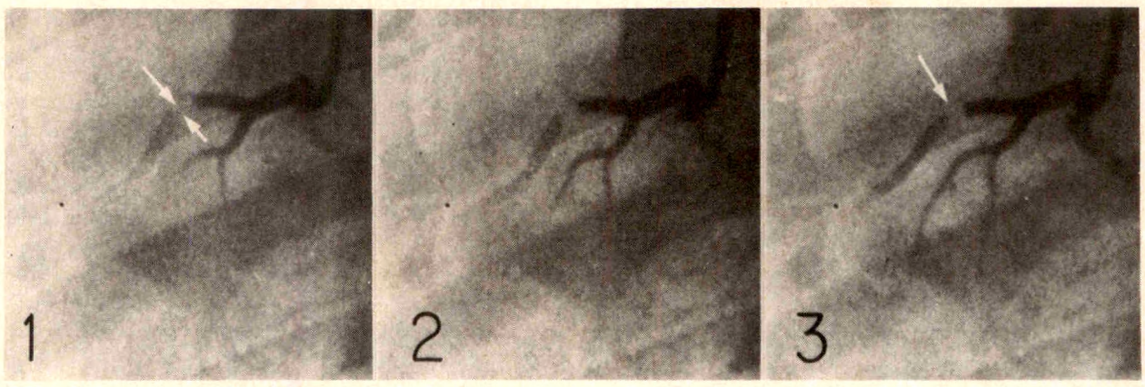

FIGURE 3. Selected sequential frames from a contrast cineangiogram of the left anterior descending coronary artery of one of the animals (0331) used in the study. In **frame 1** the contrast material appears to taper toward the center of the vessel (**area between the two arrows**). In **frame 2** a small centrally placed nub is apparent on the proximal end of the column of dye. In **frame 3** the column of contrast medium proximal as well as distal to the stenosis (radiolucent zone indicated by **arrow**) is squared off. The sequence of images suggests that contrast medium first passes through the central lumen of the stenosis and that blood does not flow around its sides. Note that the distal artery appears to fill at roughly the same rate as the diagonal branches proximal to the stenosis. The resolution of the angiographic system used in this study was 1.5 to 2.0 line pairs/mm.

used. The roentgenographic system employs a fine line grid containing 60 lines with 6 to 1 ratio. It has a 0.6 mm focal spot with tube to film a distance of 28 inches (711.2 mm). Resolution of the system is 1.5 to 2.0 line pairs/mm.

After halothane (0.5 to 1.5 percent) anesthesia was discontinued, all cutdown sites were closed and all catheters secured in place. Next, the animal was moved to a special cage and allowed to awaken from the anesthesia. The animal remained intubated and spontaneously breathed a mixture of 50 percent oxygen and 50 percent nitrous oxide throughout the remainder of the study. The endotracheal tube was suctioned and the animal sighed with a bag inflation device at regular intervals to maintain arterial pH, and partial pressures of carbon dioxide and oxygen within the physiologic range. Heart rate was monitored continuously from the electrocardiogram (lead V_1); arterial, left atrial and pulmonary arterial pressures were also monitored continuously. Sodium thiamylal was given in small doses (20 to 40 mg intravenously) as needed (usually every 60 to 90 minutes) to ensure that the animal rested quietly in its cage. Although sedated, the animal was responsive and had brisk corneal reflexes.

Regional myocardial blood flow was determined by injecting 4 million radiolabeled microspheres (diameter 15 μ) (New England Nuclear, Billerica, Massachusetts) into the left atrium. At the same time a 2 minute reference collection of arterial blood was obtained by means of a Harvard pump. The microspheres were suspended in a solution of 10 percent dextran and 0.01 percent Tween 80™ and sonically dispersed for 15 minutes before injection. A different radioisotope (chosen at random) was used for each injection. Total radioactivity for each injection ranged from 85 to 105 μCi.

After control measurements of hemodynamics and regional myocardial blood flow were made, the animal's heart rate was increased for 10 minutes by atrial pacing at 185 to 190 beats/min. A second set of microspheres was given and pacing discontinued after completion of the reference collection of arterial blood. Ten to 15 minutes later, after heart rate and arterial pressure had stabilized at control levels, a third set of microspheres was given. Cardiac output (green dye technique) was determined just before each injection of microspheres.

In one of the six animals regional myocardial blood flow also was determined during intravenous infusion of adenosine (0.59 mg/kg per min × 10 min). The vasodilator infusion was begun after completion of the second control determination of regional myocardial blood flow. Microspheres were injected at the end of the drug infusion period.

After the completion of flow studies, the animal was removed from its cage and placed on the angiography table. Next, the left anterior descending coronary artery was selectively catheterized, after which a repeat cineangiogram was recorded with identical roentgenographic technique and positioning comparable to that of the initial film. The animal was then killed by injection of potassium chloride directly into the heart.

Postmortem examination: The heart was removed and the location of the stenosis marked with a silk suture. It was then thoroughly washed in tap water and blotted dry. Next the left anterior descending coronary was opened by inserting a Metzenbaum scissor into its orifice and cutting it open along its entire length. The artificial stenosis was removed and inspected for evidence of fibrin deposition or blood clot within its lumen. The surface of the artery was inspected for evidence of dissection or intimal damage.

The heart was then divided into two zones, one encompassing the posterobasal region in an area perfused by the circumflex coronary artery and another along the anterior wall of the left ventricle in a region perfused by that part of the left anterior descending artery which was distal to the stenosis (distal zone). This area was defined visually by following the epicardial distribution of its diagonal branches. Each region in turn was subdivided into cubes weighing approximately 1 g. Each cube was further divided into endocardial and epicardial halves. The samples were placed in preweighed tubes, and the tube and contents reweighed. The radioactivity in each was determined by counting the samples in a gamma well counter (Packard Instruments, Downers Grove, Illinois). A computer was used to correct for spillover of counts from one isotope into the window of another and to calculate regional blood flow in the samples.

Statistical methods: All data are expressed as mean ±1 standard deviation. The null hypothesis that two or more treatment means (such as regional myocardial blood flow in a given zone during and after atrial pacing) did not differ significantly ($p < 0.05$) from that of the control mean (such as regional myocardial blood flow given zone before pacing) was tested by means of a blocked one way analysis of variance and Dunnett's test.[13] The value F for the treatment effect (F[t]) and associated value of p are given for all tests involving regional myocardial blood flow in which the p value is 0.05 or greater.

Results

Technical aspects: Placement of the artificial stenosis was successful in all six cases. Each stenosis lodged within the proximal one third of the left anterior descending coronary artery. The device remained patent for the duration of the study (5.1 ± 0.5 hours) in all six animals. Cineangiograms obtained at the start and finish of each case revealed slight (2 mm) distal migration of the stenosis in only one instance. In all other cases the device did not move from its original location. No angiographic or electrocardiographic evidence of coronary arterial spasm was observed in any animal. Inspection of cine films revealed no evidence of contrast medium passing around the sides of the lesion in any study (Fig. 3). Further, in five of six animals cineangiograms as well as postmortem examination of the heart revealed no evidence of occlusion of any branch of the left anterior descending coronary artery. In the remaining animal a small septal branch was occluded by the stenosis. This was readily apparent when the stenosis was removed because (1) the device was recovered from a position directly over the orifice of the branch, and (2) there was a clearly defined peninsula of pale yellow-tan tissue surrounding the vessel in question. Microsphere activity (all three isotopes) in this specimen was negligible. Finally, there was prompt anterograde filling of the left anterior descending coronary artery beyond the stenosis in all animals (Fig. 3), a finding that suggests that simultaneous retrograde filling of the vessel was unlikely.

There was no gross evidence of damage to the intimal lining of the left anterior descending coronary artery in any animal. Likewise there was no gross evidence of platelet or fibrin deposition within the lumen of the bead.

Regional myocardial blood flow (Table I, Fig. 4): Regional myocardial blood flow distal to the stenosis was compared with that in the circumflex arterial zone

TABLE I

Regional Blood Flow (ml/min per g) in Myocardium Distal to an Artificial Stenosis of the Left Anterior Descending Artery (distal zone) and in Myocardium Perfused by a Normal Coronary Artery (circumflex zone)

	Control I	Atrial Pacing	Control II
Distal zone			
Transmural	1.28 ± 0.34	1.45 ± 0.40	1.28 ± 0.42
Endocardium	1.26 ± 0.34	1.16 ± 0.37	1.20 ± 0.41
Epicardium	1.28 ± 0.37	1.72 ± 0.48*	1.35 ± 0.47
Endo/epi ratio	0.99 ± 0.13	0.68 ± 0.14*	0.91 ± 0.17
Circumflex zone			
Transmural	1.31 ± 0.31	1.73 ± 0.27*	1.34 ± 0.38
Endocardium	1.37 ± 0.11	1.82 ± 0.33*	1.42 ± 0.40
Epicardium	1.26 ± 0.36	1.65 ± 0.24*	1.26 ± 0.37
Endo/epi ratio	1.10 ± 0.11	1.10 ± 0.08	1.14 ± 0.07
Distal to circumflex zone flow ratio			
Transmural	0.97 ± 0.10	0.82 ± 0.11*	0.95 ± 0.10
Endocardial	0.92 ± 0.13	0.63 ± 0.14*	0.84 ± 0.15
Epicardial	1.01 ± 0.11	1.02 ± 0.15	1.06 ± 0.11

* $p < 0.01$ versus control I.
Endo = endocardium; Epi = epicardium.

for each phase of the study. At rest the ratio of transmural flow for the two zones was 0.97 ± 0.10. Compared with the control level (1.28 ± 0.32 ml/min per g), transmural flow in myocardium distal to the stenosis did not change significantly during (1.45 ± 0.40) or after (1.28 ± 0.42) atrial pacing ($F[t] = 1.799$, $p = 0.22$). In contrast, flow in the circumflex arterial zone increased with pacing from a control value of 1.31 ± 0.31 to 1.73 ± 0.27 during pacing ($p < 0.01$) and then returned to a level similar to the initial control level (1.34 ± 0.38) after discontinuation of pacing. As a result, the transmural flow ratio (distal to circumflex) decreased to 0.82 ± 0.11 ($p < 0.01$) during pacing but returned to the initial control level (0.95 ± 0.10) 10 minutes after pacing was stopped.

Endocardial blood flow distal to the stenosis decreased from a control value of 1.26 ± 0.34 to 1.16 ± 0.37 during atrial pacing and returned to a level similar to the control value (1.20 ± 0.41) 10 minutes after pacing was terminated ($F[t] = 0.544$, $p = 0.60$). In contrast, endocardial flow in the circumflex zone increased from a control level of 1.37 ± 0.11 to 1.82 ± 0.33 during atrial pacing ($p < 0.01$) and returned to control levels (1.42 ± 0.40) when pacing was terminated. The endocardial blood flow ratio (distal to circumflex) decreased from 0.92 ± 0.13 to 0.63 ± 0.14 ($p < 0.01$) during pacing and returned toward control after pacing was discontinued (0.84 ± 0.15).

Epicardial blood flow during atrial pacing increased significantly ($p < 0.01$) and to a comparable extent in epicardium distal to the stenosis (1.72 ± 0.48 versus control 1.28 ± 0.37) and in the circumflex zone (1.65 ± 0.24 versus control 1.26 ± 0.36). Epicardial flow returned to control levels (1.35 ± 0.47 and 1.26 ± 0.37, respectively) after pacing was discontinued. The epicardial blood flow ratio (distal to circumflex) did not change significantly compared with the control value (1.01 ± 0.11) during (1.02 ± 0.15) or after (1.06 ± 0.11) atrial pacing ($F[t] = 0.835$, $p = 0.46$).

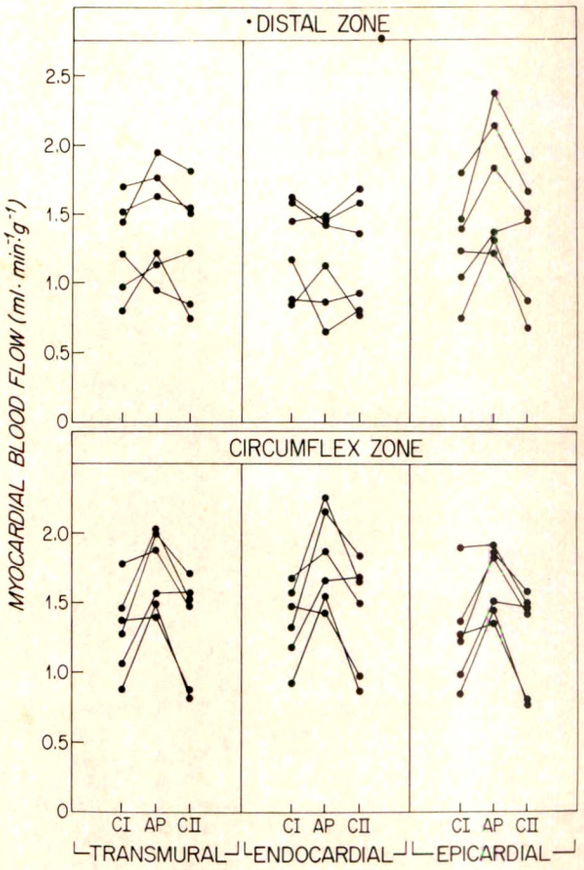

FIGURE 4. Regional myocardial blood flow (ml/min per g) for each phase of the study is shown for transmural, endocardial and epicardial samples distal to the left anterior descending arterial stenosis (**top**) and in the circumflex arterial region (**bottom**). Each point represents one animal. Note that compared with control I (CI), transmural flow during atrial pacing (AP) increased significantly in the circumflex zone but not in the distal zone. Endocardial flow increased significantly during atrial pacing only in the circumflex area. Flow was augmented in epicardial samples during atrial pacing to a comparable extent in both the distal and circumflex regions. After cessation of atrial pacing (CII), flow in all samples returned to levels that did not significantly differ from that of control I.

Finally, the endocardial to epicardial blood flow ratio in the distal zone decreased from 0.99 ± 0.13 to 0.68 ± 0.14 during atrial pacing ($p < 0.01$) and then returned to control (0.91 ± 0.17) after pacing was stopped. In contrast, the endocardial to epicardial flow ratio in the circumflex region did not change significantly from the control value (1.1 ± 0.11) during (1.1 ± 0.08) or after (1.14 ± 0.07) atrial pacing ($F[t] = 1.085$, $p = 0.37$).

Infusion of adenosine in one animal resulted in marked disparity between transmural flow in the circumflex and distal left anterior descending zones (Fig. 5). Thus transmural flow more than tripled (1.49 to 4.91) in the circumflex zone, whereas it increased by only 11 percent (1.51 to 1.69) in the zone distal to the stenosis. Further, endocardial blood flow distal to the stenosis remained essentially fixed, whereas in the circumflex zone it increased considerably in response to adenosine and to a lesser extent in response to atrial pacing. Epicardial blood flow distal to the stenosis increased

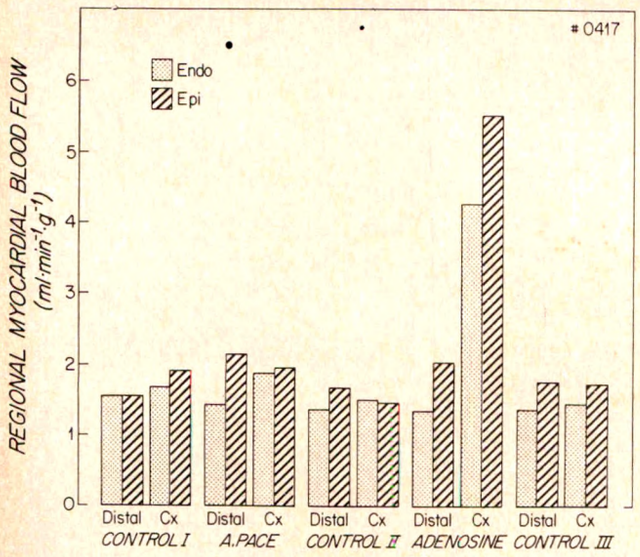

FIGURE 5. Regional myocardial blood flow (ml/min per g) in one animal (0417) that was given adenosine to test the vasodilatory reserve of the distal left anterior descending (Distal) and circumflex (Cx) coronary arterial beds. Note that compared with control period I, endocardial blood flow distal to the stenosis remained unchanged after atrial pacing (A. Pace) and adenosine infusion. In contrast, endocardial flow in the circumflex region increased moderately in response to pacing and markedly in response to adenosine infusion. Blood flow in epicardium distal to the stenosis increased to an extent comparable with that in the circumflex region during atrial pacing. However, during infusion of adenosine, epicardial flow in the circumflex zone greatly exceeded that in the distal zone. Note also that epicardial flow in the distal zone was essentially the same during both interventions.

modestly and to a comparable extent in response to both pacing and adenosine infusion.

Hemodynamics: Hemodynamic observations associated with each phase of the study were as follows. In response to atrial pacing the rate-pressure product (mm Hg/min $\times 10^2$) increased from 140 ± 47 to 262 ± 24 ($p < 0.001$) and then decreased to 137 ± 35 after cessation of pacing. Mean left atrial pressure during atrial pacing (13.7 ± 4.9 mm Hg) was significantly higher ($p < 0.01$) than either before (5.5 ± 2.6) or after (5.0 ± 3.2) pacing. Diastolic arterial pressure did not change significantly during the study (114 ± 9 mm Hg before pacing, 115 ± 11 with pacing and 118 ± 8 after pacing). Cardiac output decreased modestly but significantly ($p < 0.05$) during (4.4 ± 0.8 liters/min) and after pacing (4.4 ± 1.0 liters/min) compared with prepacing the level (4.9 ± 0.9 liters/min).

Discussion

Demonstration of experimentally produced critical coronary stenosis: The present study demonstrates that a critical intraluminal coronary arterial stenosis can be created and maintained for over 5 hours in a closed chest animal. The data obtained from the pacing part of the study confirm that a critical stenosis was produced by the device. Thus, although transmural blood flow distal to the left anterior descending arterial stenosis was similar at rest to that in the circumflex arterial zone, it failed to increase significantly in the distal area during atrial pacing. Further, both the transmural and endocardial distal to circumflex flow ratios decreased significantly during atrial pacing and then returned to control levels after pacing was discontinued. In addition, during pacing the endocardial to epicardial flow ratio decreased considerably in myocardium distal to the stenosis but remained unchanged in the circumflex zone. Thus our data indicate that the subendocardial layer of the heart is most vulnerable to ischemia, an observation consistent with the results of previous studies by other investigators.[14–17] In addition, our data indicate that some vasodilator reserve persists in epicardial vessels distal to a critical coronary stenosis. This finding is in accord with the results of a recent study by Gallagher et al.[17] Finally, it should be noted that others[18,19] have observed that resting blood flow may be decreased distal to an extraluminal artificial stenosis that is 5 mm long and that decreases luminal diameter by only 60 percent. The reason for this difference from our results is uncertain, but it may well be related to differences in the way in which the stenosis was created (that is, intraluminal versus extraluminal placement) as well as other differences in method (for example, open versus closed chest animals, general anesthesia versus mild sedation, and species differences between the dog and the pig). Whatever the reason for this difference, our data, nevertheless, show that the intraluminal stenosis impairs flow when the animal is stressed and that such changes are reversible when the stress is removed. Taken together our findings support the contention that a critical stenosis was produced by the device.

Advantages of the method: In addition to the speed and ease with which the artificial stenosis can be created, this technique offers other advantages. First, open chest surgery with its attendant trauma and alterations in the normal physiologic characteristics of the pericardium is avoided. In addition, possible disruption of normal myocardial and coronary arterial nerve supply is also avoided. Second, the ability to place a critical lesion of known dimensions within the lumen of the coronary artery allows one to assess its effects on regional function and blood flow during a stress intervention without introducing experimental errors that could be caused by decreasing flow under resting conditions. Third, because the artificial stenosis causes a rigid lesion with a constant exit angle and a fixed diameter, its effects on regional myocardial blood flow can be assessed in the absence of factors (such as spasm or collapse of the vessel at the site of the lesion) that could change the geometric characteristics of the lesion and thereby alter its severity.[20–23] The fixed proximal nature of the stenosis also should be helpful for studying the effects of a change in peripheral coronary arteriolar resistance on regional myocardial blood flow. Fourth, by placing an artificial stenosis in any or all of the other coronary arteries one could model multivessel coronary disease.

Limitations of the method: Despite its advantages this technique has limitations that may reduce its utility in some circumstances. It is possible for the device to

occlude a side branch of the artery into which it is inserted and thus produce a small zone of ischemia or infarction. Depending on the nature of the study, this occurrence (which is easily recognized) may or may not require that the animal be eliminated from the data analysis. Although the precise location within a given coronary artery cannot be controlled, the dimensions of the stenosis will dictate whether it comes to rest in the proximal, mid or distal portion of the vessel. The highly flexible nature of the guide wire and pushing catheter make it impossible to advance a device 3.5 mm in diameter into a more distal portion of a vessel with a substantially smaller diameter. Nevertheless, if for some reason the artificial stenosis had to be precisely positioned at a very specific portion of the vessel, problems could arise because of an inability to control the exact location where the stenosis comes to rest. In addition, once the device has been inserted it is not possible to adjust its position or remove it.

Adaptation of method to acute and long-term physiologic studies: One reason this method was developed was to avoid technical and physiologic problems associated with coronary arterial surgery in the preparation of animals for physiologic studies. In this regard, the microsphere technique was chosen to measure regional myocardial blood flow because it is very easy to catheterize the left atrium and thereby administer microspheres without having to operate on the animal. The microsphere technique itself has been extensively validated by Domenech et al.[12] and Heymann et al.[24] At present it is the most reliable and readily available way to assess the transmural distribution of regional myocardial blood flow in the same animal under a variety of conditions. However, if one wished to study coronary flow velocity with a flow probe or regional myocardial function with ultrasonic crystals, there is no reason why the artificial stenosis could not be inserted first and the required surgery and instrumentation performed immediately thereafter. The animal could then be used for acute open chest studies. Even under these conditions the intraluminal fixed nature of the lesion would offer an advantage over conventional methods of creating a critical coronary stenosis. Furthermore, although it might be difficult to maintain systemic anticoagulation for 1 or 2 weeks in order to permit the animal to recover from surgery, it would be possible. Accordingly, it should be possible to adapt this technique for use in chronically instrumented animals.

In summary, we have developed a simple and effective method for creating a critical intraluminal coronary arterial stenosis in a closed chest laboratory animal. This method makes it possible to avoid many of the problems associated with open chest surgery and general anesthesia in the preparation of animals for studies requiring a critical coronary arterial lesion. The technique does have certain limitations. Nevertheless, the ability to create and maintain a fixed, critical, intraluminal coronary arterial stenosis in a closed chest animal provides an improved model for the study of myocardial blood flow and left ventricular function.

The effects of intracoronary diatrizoate meglumine and diatrizoate sodium (Renografin-76) on regional contraction were examined in the normal coronary circulation and during partial (50 percent) coronary occlusion in 11 dogs using strain and length gauges. Intracoronary injections of Renografin-76 (1.5 cc) (1,690 mosM/liter; 0.19 mEq Na/ml), equiosmolar dextrose solution and 0.19 mEq Na^+/ml saline solution were made randomly. Renografin-76 caused a decrease in preejection tension to 87.4 ± 4.3 percent ($p < 0.025$), total tension to 74.6 ± 3.3 percent ($p < 0.01$) and ejection tension to 11.9 ± 12.6 percent ($p < 0.001$) of control value. Segment length increased to 106.7 ± 7.3 percent of control value. These changes lasted only 12 ± 2 (range 5 to 20) seconds (mean ± standard error of the mean). During partial coronary occlusion and after injection of Renografin-76, preejection tension decreased from 91.7 ± 6.3 to 53.8 ± 3.9 percent ($p < 0.01$), total tension from 89.9 ± 5.0 to 59.7 ± 3.5 percent ($p < 0.01$) and ejection tension from 22.8 ± 8.1 to 17.8 ± 10.9 percent, whereas segment length increased from 112.7 ± 3.7 to 130.7 ± 4.6 percent ($p < 0.01$) of control value. In contrast to findings in the normal coronary circulation, tension and length changes lasted 54 ± 16 (range 15 to 180) seconds ($p < 0.05$). The hyperemic response during normal coronary circulation was completely abolished during partial coronary occlusion. Prior administration of nitroglycerin did not shorten the duration of the myocardial depressant effects of Renografin. Injections of equiosmolar dextrose or saline solution produced qualitatively similar but quantitatively less marked changes. Thus, intracoronary Renografin-76 has an accentuated and prolonged depressant effect on the ischemic as compared with the normally perfused myocardium; this effect is not solely due to its hyperosmolarity or sodium concentration.

Selective coronary arteriography is being widely used in the evaluation of patients with coronary artery disease. Although the morbidity and mortality associated with this technique have declined considerably with increasing experience, the attendant risks are higher in patients with acute ischemia[1,2] than in other groups. These risks may partly be related to the myocardial depressant effects of the contrast medium being used.[3–5] Although several experimental and clinical studies have evaluated the effects of the intracoronary injections of contrast material on global left ventricular performance, there is paucity of information on the regional contractile performance of the ischemic and nonischemic left ventricular zones during selective coronary injections.

The present experimental study was therefore designed to evaluate the differential effects of the intracoronary injections of a commonly used contrast medium (Renografin-76®) on the contractile function of nonischemic and ischemic myocardium after partial coronary occlusion.

Methods

Experiments were performed in 17 mongrel dogs, weighing 25 to 30 kg, anesthetized with sodium pentobarbital (30 mg/kg body weight, intravenously), intubated and ventilated with room air using a Harvard respirator. Electrocar-

diographic lead I or II, or both, was recorded continuously in each experiment. Aortic pressure was monitored with use of a stiff catheter positioned in the ascending aorta. A 3F radiopaque catheter was positioned in either the left anterior descending or the circumflex coronary artery using the method described previously.[6] A left anterolateral thoracotomy was performed and the heart was supported in a pericardial cradle. A 2 to 3 cm long segment of the coronary artery was exposed and mobilized. A specially designed adjustable screw clamp was passed around the coronary artery proximal to the tip of the intracoronary catheter for producing graded reduction in coronary blood flow.[7] An electromagnetic flow probe (Micron MV 1001-B) was sequentially placed distal to the tip of the catheter to monitor coronary flow distal to the occlusion.

Two Walton-Brodie strain gauge arches were placed with deep sutures at a 30 to 40 percent stretch, one in the area subserved by the vessel containing the intracoronary catheter (potentially ischemic zone) and the other in the remote unaffected area (nonischemic zone). A previously calibrated mercury-in-Silastic® segment length gauge was also sutured adjacent and parallel to the strain gauge arch in each zone.[6–8]

Partial coronary occlusion was produced by tightening the adjustable microscrew clamp around the coronary artery and monitoring distal coronary flow until a stable 50 percent (45.3 ± 3.6) reduction in coronary flow was achieved. At least 15 minutes was allowed for the contractile function to stabilize after partial coronary occlusion.

Intracoronary test solutions: The following solutions (1.5 cc each) were injected into the coronary artery through the radiopaque catheter in random order before and at least 15 minutes after partial coronary occlusion and their effect elucidated on the contractile function and coronary blood flow to the partially ischemic and nonischemic myocardium: (1) Renografin-76® (diatrizoate meglumine and diatrizoate sodium); (2) glucose solution containing 1,690 milliosmoles/liter; and (3) saline solution (0.19 mEq Na^+/ml). The osmolarity of the latter two solutions was similar to that of Renografin-76. Renografin (1.5 cc) was sufficient for adequate visualization of the coronary artery on fluoroscopy. All three solutions were injected at a temperature of 37° C and the duration for each injection was kept constant at 2 to 3 seconds. At least 10 minutes was allowed between injections for the effect of the previous injectate to dissipate and all measurements of contractile parameters to return to baseline.

In six experiments, 300 to 400 μg bolus dose of intravenous nitroglycerin was injected before the injection of Renografin-76 to test whether the myocardial depressant effects of intracoronary Renografin could be prevented by prior administration of nitroglycerin.

Measurements: As an index of contractile performance of the myocardium, the following variables were measured and expressed as percent of control value before and after each injection: (1) total tension, (2) preejection tension, (3) ejection tension, and (4) phasic segment length. Continuous recordings of segment tension and length were made on an Electronics for Medicine oscilloscopic recorder at paper speeds of 50 to 100 mm/s. The duration of depressant effects of each intervention was interpreted as the time from the completion of the injection to the return of contractile variables to baseline. Statistical analysis was performed by Student's *t* test for paired values.

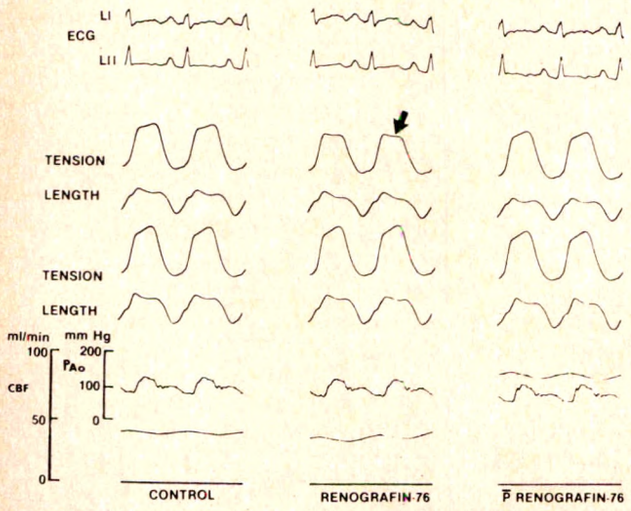

FIGURE 1. Effect of intracoronary injection of Renografin-76 on segment tension, length and coronary blood flow of the nonischemic zone. Recordings (**from top to bottom**) include electrocardiographic (ECG) leads I and II, tension and length from the potentially ischemic zone before coronary occlusion, tension and length from the nonischemic remote zone, aortic pressure (P_{Ao}) and coronary blood flow (CBF). The injection of Renografin-76 causes a rapid diminution in the ejection phase of tension development, marked by a negative slope (**arrow**) in addition to a decrease in preejection and total tension. There was no significant change in segment length. The changes in segment tension were immediately reversible. There was a marked increase in coronary blood flow immediately after the injection indicating a hyperemic response.

Results

Effect of Renografin-76 on normally perfused myocardium: Figure 1 demonstrates the characteristic pattern of tension and segment length changes before and after intracoronary injection of Renografin-76. Immediately after the completion of the injection, there was a rapid and progressive diminution of tension development in the ejection phase marked by a negative slope. In addition, the preejection and total tensions were reduced significantly. Segment length did not show a significant change. The changes in tension and length returned to control levels within 5 to 20 seconds (mean ± standard error of the mean 12 ± 2) after injection of Renografin-76 (Fig. 2).

The quantitative changes in tension and length variables are demonstrated in Figure 3. The intracoronary injection of Renografin-76 caused significant decreases in preejection tension to 87.4 ± 4.3 percent ($p < 0.025$), total tension to 74.6 ± 3.3 percent ($p < 0.01$) and ejection tension to 11.9 ± 12.6 percent ($p < 0.001$) of control values. Phasic segment length increased insignificantly to 106.7 ± 3.7 percent of control value.

Coronary flow showed a marked hyperemic response after the injection of Renografin-76 (Fig. 1). There was a transient 1.8 to 3.8-fold (mean 2.5 ± 0.2) increase in coronary blood flow (from 38.2 ± 3.7 to 95.4 ± 6.9 ml/min) that reached a peak 7 to 12 seconds after the injection and slowly returned to control value over 2 minutes.

Effect of Renografin-76 on ischemic myocardium (Fig. 4 to 6): Partial coronary occlusion (45.3 ± 3.6 percent reduction in coronary blood flow) caused significant reduction in preejection tension to 91.7 ± 6.3 percent ($p < 0.05$), total tension to 89.9 ± 5.0 percent (p

<0.01) (Fig. 4) and ejection tension to 22.8 ± 8.1 percent (p <0.001) of control values. Segment length increased to 112.7 ± 3.7 percent (p <0.025) of control value. After injection of Renografin-76, the preejection tension decreased from 91.7 ± 6.3 to 53.8 ± 3.9 percent (p <0.01) and total tension decreased similarly from 89.9 ± 5.0 to 59.7 ± 3.5 percent of control value (p <0.01) (Fig. 4). Ejection tension was reduced from 22.8 ± 8.1 to 17.8 ± 10.9 percent of control value. Phasic segment length, which had increased to 112.7 ± 3.7 percent after partial coronary occlusion increased further to 130.7 ± 4.6 percent of control value (p <0.01) (Fig. 4). In contrast to findings in the nonischemic myocardium, the changes in tension and length were prolonged and returned to control value (post-coronary occlusion level) in 15 to 180 (mean 54 ± 16) seconds (p <0.05) after injection of Renografin-76 (Fig. 5).

The coronary flow through the partially occluded vessel actually decreased from 20.6 ± 2.5 to 14.8 ± 2.6 ml/min after injection of Renografin-76, returning to preinjection levels in 10 to 110 seconds. Hyperemic response was completely abolished (Fig. 6).

Comparative effects of Renografin-76, hypertonic dextrose and hypertonic saline solutions (Figs. 7 and 8): After intracoronary injections of hypertonic dextrose or hypertonic saline solution, the changes in preejection tension, ejection tension, total tension and segment length were qualitatively similar but quantitatively less marked than those produced by Renografin-76 in both normally perfused and ischemic myocardium. The peak hyperemic coronary flow after injection of hypertonic saline or dextrose solution correlated well with that produced by Renografin-76 (r = 0.92) in the normally perfused myocardium. However, the hyperemic response was abolished after partial coronary occlusion.

Effect on remote myocardium, heart rate and blood pressure: The tension and length parameters in the remote myocardium unperfused by the vessel injected with Renografin-76 or saline or dextrose solution remained unchanged following injection of each agent. Similarly, the heart rate and blood pressure remained unaffected by the intracoronary injections both when the myocardium was normally perfused and during partial coronary occlusion.

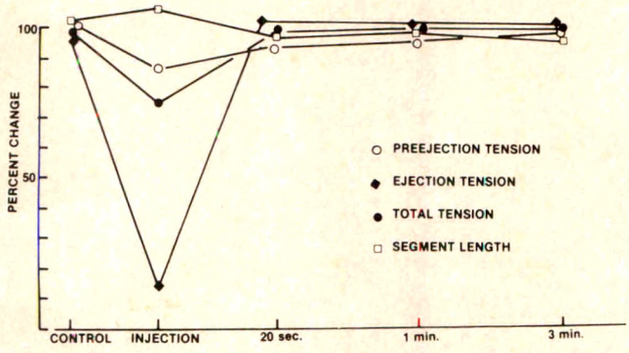

FIGURE 2. Temporal sequence of changes in tension and length variables of the normally perfused (nonischemic) myocardium after the intracoronary injection of Renografin-76.

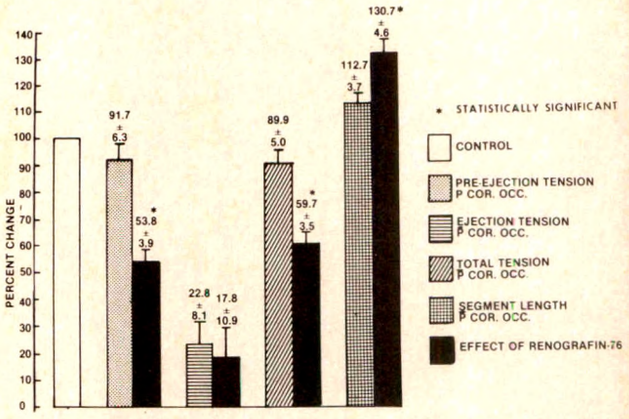

FIGURE 4. Effect of intracoronary injection of Renografin-76 on tension and length variables of the ischemic myocardium (after partial coronary occlusion [P COR. OCC.]). Values are expressed as percent of control value.

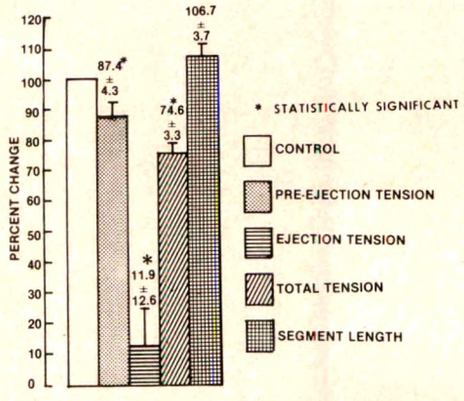

FIGURE 3. Effect of intracoronary injection of Renografin-76 on tension and length variables of the nonischemic myocardium. Values are expressed as percent of control value.

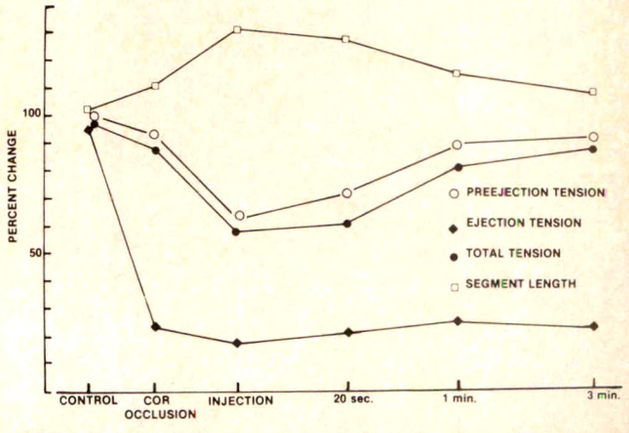

FIGURE 5. Temporal sequence of changes in tension and length variables of the ischemic myocardium (after partial coronary [COR] occlusion) after the intracoronary injection of Renografin-76.

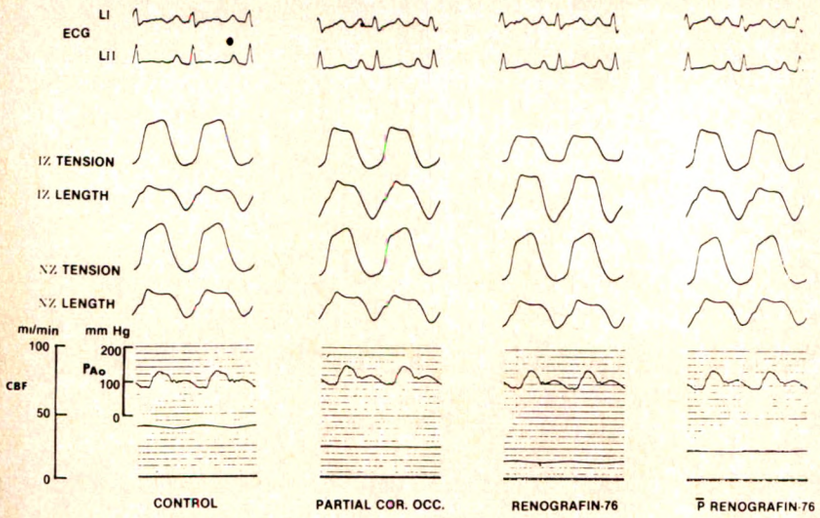

FIGURE 6. Effect of intracoronary injection of Renografin-76 on segment tension, length and coronary blood flow (CBF) of the ischemic myocardium after partial coronary occlusion. Recordings (**from top to bottom**) include electrocardiographic (ECG) leads I and II, tension and length from the ischemic zone (IZ) after partial coronary occlusion (COR. OCC.), tension and length from the nonischemic zone (NZ), aortic pressure (P_{Ao}) and coronary blood flow (CBF). Partial coronary occlusion produced a significant decrease in tension with loss of ejection tension and increase in segment length. After (P) the injection of Renografin-76, there was further decrease in tension and increase in length of the ischemic zone which returned to near post-coronary occlusion levels after 54 ± 16 seconds. Coronary blood flow decreased further after injection of Renografin-76 and did not show a hyperemic response after the injection (compare with Fig. 1).

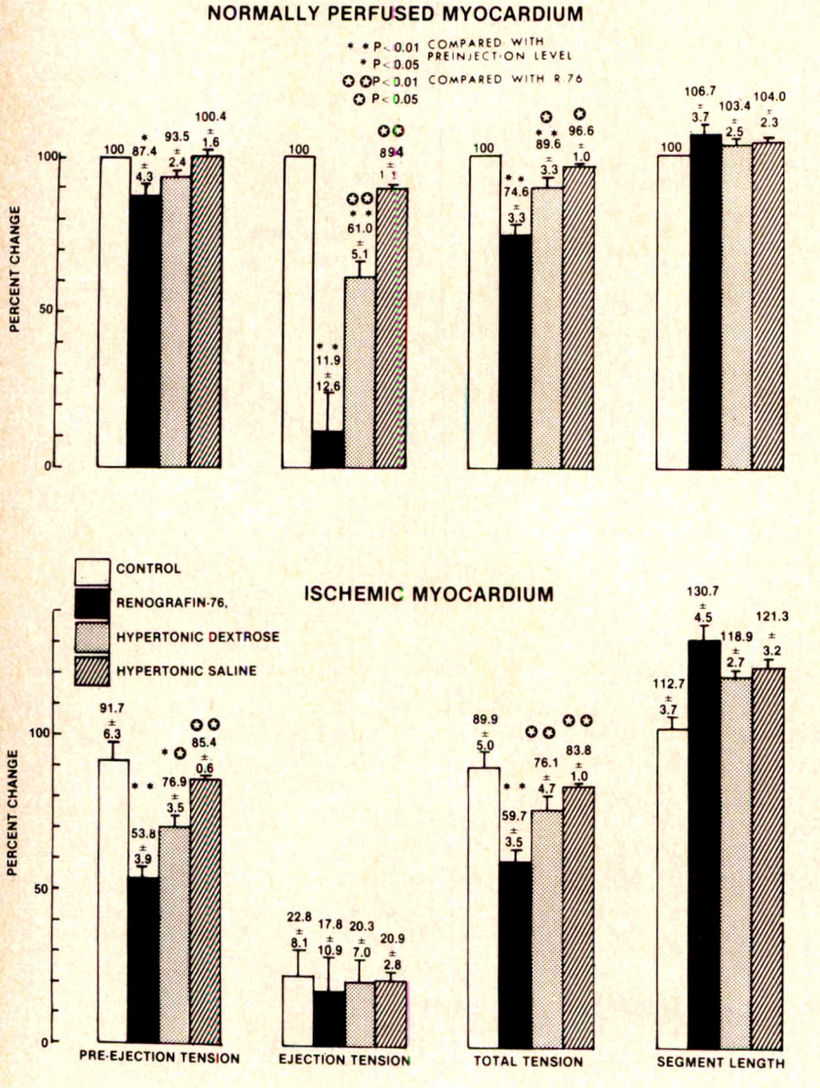

FIGURE 7. Comparative effects of intracoronary injection of Renografin-76 (R-76), and hypertonic dextrose and hypertonic saline solutions on normally perfused and ischemic myocardium. Values are expressed as percent of control value.

Effect of nitroglycerin on the myocardial depressant effects of Renografin-76: Prior administration of intracoronary nitroglycerin did not prevent the myocardial depressant effects of Renografin-76. In the normally perfused myocardium, injection of Renografin-76 caused the total tension to decrease to 71.3 ± 7.5 percent, preejection tension to 79.5 ± 6.9 percent and ejection tension to 35.8 ± 11.7 percent of control value. These variables returned to control value 8 to 30 (mean 15.3 ± 7.0) seconds after injection of Renografin-76.

After partial coronary occlusion and administration of nitroglycerin, the injection of Renografin-76 caused the total tension to decrease from 73.0 ± 9.8 to 60 ± 11.0 percent ($p < 0.01$), preejection tension from 76.0 ± 9.1 to 72.1 ± 8.6 percent ($p < 0.01$) and ejection tension from 50.5 ± 9.5 to −4.7 ± 3.8 percent ($p < 0.01$) of control. These variables returned to control value (post-occlusion level) in 25 to 70 (mean 46.7 ± 21.3) seconds.

Discussion

Considerable interest has been focused on the myocardial depressant effects of the contrast media used for coronary arteriography and ventriculography.[3–5,9–11] However, most studies have compared various contrast media and their ionic concentrations and osmolar aspects to determine the relative safety of each medium.[9–11] These studies have indicated that intracoronary injection of contrast medium results in a decrease in regional contraction as well as in indexes of global left ventricular performance when the coronary perfusion is normal. However, there is little information about the effects of contrast medium on regional performance of the ischemic myocardium. A recent study by Sos and Baltaxe[12] indicates that in patients with coronary disease, there is little difference in the left ventricular ejection fraction as well as regional contractility fraction in the ventriculograms performed before and after coronary arteriography.

Myocardial depressant effects of contrast medium on normal and ischemic myocardium: The present study indicates that when Renografin-76 is injected into a coronary artery, the subserved myocardial zone demonstrates a marked loss in ejection tension and total tension and a slight increase in segment length (Fig. 1) These changes are essentially similar to those produced by the effects of transient coronary occlusion manifesting as an immediate loss of ejection tension, a negative slope in the ejection phase of tension development and a decrease in preejection and total tension.[8] A negative change in ejection tension was not seen when equiosmolar solutions (hypertonic saline and hypertonic glucose) were injected (Fig. 8), thereby indicating that the myocardial depressant effect of Renografin-76 is not dependent on its hyperosmolarity. The contractile changes in the presence of an unobstructed coronary artery were essentially transient and were reversible in less than 20 (mean 12 ± 2) seconds (Fig. 2). In contrast to the effects of an injection made in a normal coronary artery, when partial coronary occlusion (45.3 ± 3.6 percent reduction in coronary blood flow) was produced, the effects of intracoronary injection of Renografin-76 lasted considerably longer (15 to 180 seconds, mean 54 ± 16) (Fig. 5). Renografin-76 produced further augmentation in the decrease in regional preejection tension, ejection tension, total tension and the increase in phasic segment length produced by partial coronary occlusion (Fig. 4). This study thus indicates that the myocardial depressant effects of an intracoronary injection of Renografin-76 in the ischemic zone are more pronounced than in the normally perfused myocardium and are 4–5 times more prolonged. Neither of these effects could be abolished by prior administration of nitroglycerin.

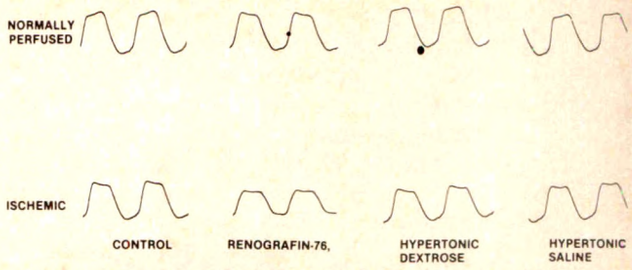

FIGURE 8. Comparative effects of Renografin-76 and hypertonic dextrose and hypertonic saline solution on tension development of the normally perfused and ischemic myocardium. Whereas intracoronary Renografin-76 produced loss of ejection tension (negative slope in ejection phase), ejection tension was maintained during injection of hypertonic dextrose or saline solution. The effects of Renografin-76 were quantitatively more marked than those produced by either of the latter solutions.

Mechanism of negative inotropic effects of contrast medium: The negative inotropic effect of contrast medium has been thought to be related to the medium's hyperosmolarity, high sodium concentration, absence of calcium ions, or the induced transitory ischemia.[13–15] In the present study, neither of the equiosmolar solutions (hypertonic saline or glucose) decreased the indexes of regional contraction to the extent produced by Renografin-76, although glucose had a more depressant effect than did saline (Fig. 7 and 8). In their clinical studies, Cohn and co-workers[16] showed that intraventricular injection of glucose and of Renografin-76 had quantitatively different effects on systemic hemodynamics. These observations suggest that neither hyperosmolarity nor the sodium concentration, in itself, is the sole factor causing myocardial depression.

Role of coronary flow reserve: Previous studies have shown that the intracoronary injection of contrast medium produces a rapid increase in coronary blood flow (hyperemic flow) followed by a gradual decrease to control levels.[14] When coronary flow reserve (that is, autoregulatory reserve) is exhausted, as in situations in which coronary stenosis is severe enough to reduce flow, no increment in flow is observed after the injection of contrast medium.[17–19] Recently, this coronary flow response after injection of contrast medium has been used for assessing coronary flow reserve in man.[20] In the

present study, the diminished myocardial contraction caused by Renografin-76 in the presence of a normal coronary circulation, was restored immediately during hyperemic flow. In contrast, after partial coronary occlusion, the myocardial depressant effects of Renografin-76 on the ischemic myocardium were relatively persistent and associated with a further reduction in coronary flow in contrast to the hyperemic flow observed in the unobstructed coronary artery. Thus, coronary flow reserve appears to play an important role in determining the duration of the depressant effects produced by injection of contrast medium. These findings are consistent with the clinical observations of Gensini et al.,[21] who demonstrated that among various patients, the increase in left ventricular end-diastolic pressure after coronary arteriography was most significant in those with severe coronary artery disease. They assumed that these findings were due to diminished myocardial contraction resulting from ischemic or fibrotic changes, or both.

Prior administration of nitroglycerin did not shorten the duration of the myocardial depressant effects of Renografin-76 on the ischemic myocardium in our study. This finding further supports the observation that, in the presence of a fixed coronary stenosis, coronary flow reserve may be an important determinant of the prolonged duration of the myocardial depressant effects of the contrast medium.

Clinical implications: There is still debate regarding the indications for coronary arteriography in patients with acute ischemic heart disease. Although the incidence of complications of coronary arteriography has decreased since the time when Renografin-76 was adopted as the contrast medium of choice,[22] these patients are still believed to be a high risk group. Because of the increased severity and prolonged duration of myocardial depressant effects of the contrast medium on the ischemic myocardium, sufficient time should be allowed between coronary injections. Although it is difficult to extrapolate experimental observations to clinical situations, our data may be particularly relevant to coronary injections in the presence of left main coronary arterial stenosis. In the presence of a critical left main stenosis sufficient to abolish hyperemic response to the contrast medium, severe and persistent myocardial depressant effects may jeopardize an extensive mass of the left ventricular myocardium and thus produce severe hypotension or left ventricular failure, or both. The risk of coronary arteriography is recognizably high in this group of patients.

The monitoring functions you really need at a price you can actually afford.

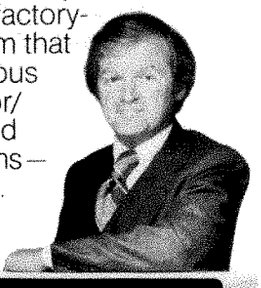
The Physio-Control CMS 6000 four-bed ECG monitoring system is designed to give you more function at lower cost.

It's a performance-oriented system, engineered to help your *existing staff* give *better care* to *more patients.*

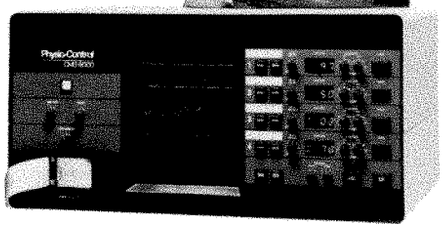
The compact central monitor unit has four channels with freeze channel and recorder. Each channel has a digital rate meter and high and low alarm limits. It couldn't be simpler. It couldn't be more reliable. It couldn't be more affordable.

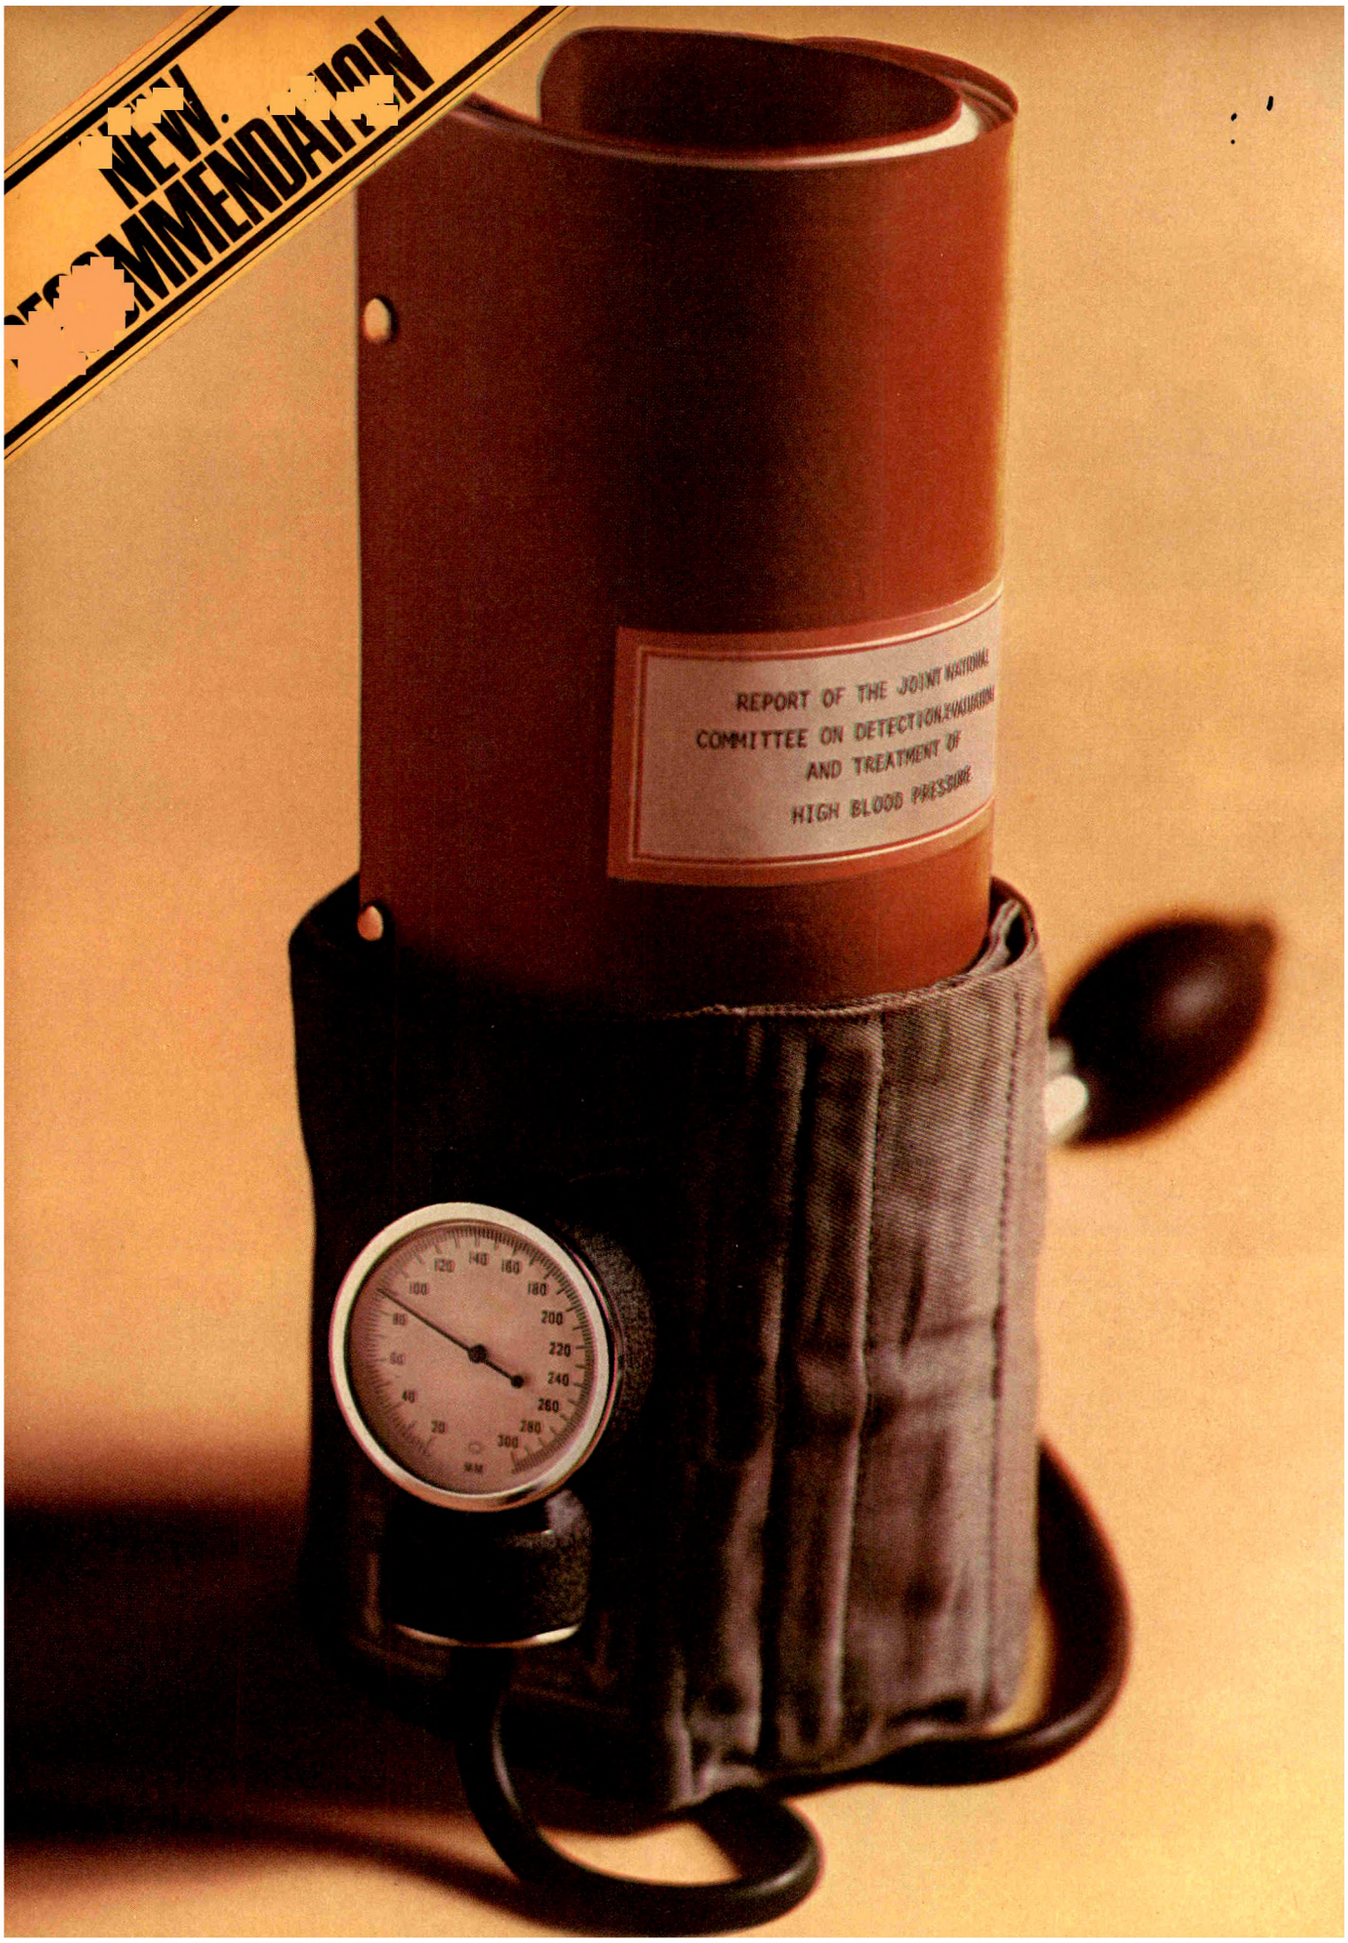
Add to that the flexibility of using portable Lifepak®6 monitors as bedside units and you have the CMS 6000—the common-sense approach to today's broad spectrum of monitoring needs.

And remember: the CMS 6000 is backed by the same nationwide factory-based service team that supports our famous Lifepak defibrillator/monitors. We stand behind our systems—*right* behind them.



The new CMS 6000 from Physio-Control





REPORT OF THE JOINT NATIONAL
COMMITTEE ON DETECTION, EVALUATION
AND TREATMENT OF
HIGH BLOOD PRESSURE

ANOTHER FIRST FOR INDERAL®
(PROPRANOLOL HCl)

NOW RECOMMENDED FOR INITIAL THERAPY IN SELECTED HYPERTENSIVE PATIENTS

"In selected younger patients with a rapid heart rate and/or high pulse pressure, beta-adrenergic blocking agents may be appropriate for Step 1 drug therapy."

—Report of the Joint National Committee on Detection, Evaluation, and Treatment of High Blood Pressure, 1980.

INDERAL®

(PROPRANOLOL HCl)

BID FOR HYPERTENSION

Please see following page for Brief Summary of Prescribing Information on Contraindications, Precautions, Adverse Reactions, and Warnings, including avoidance of abrupt withdrawal.

THE MOST WIDELY PRESCRIBED BETA BLOCKER IN THE WORLD.

INDERAL®

(PROPRANOLOL HCl)

B.I.D. FOR HYPERTENSION

BRIEF SUMMARY *(FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE CIRCULAR.)*
Inderal® BRAND OF **propranolol hydrochloride A beta-adrenergic blocking agent**

BEFORE USING INDERAL (PROPRANOLOL HYDROCHLORIDE), THE PHYSICIAN SHOULD BE THOROUGHLY FAMILIAR WITH THE BASIC CONCEPT OF ADRENERGIC RECEPTORS (ALPHA AND BETA), AND THE PHARMACOLOGY OF THIS DRUG.

CONTRAINDICATIONS

INDERAL is contraindicated in: 1) bronchial asthma; 2) allergic rhinitis during the pollen season; 3) sinus bradycardia and greater than first degree block; 4) cardiogenic shock; 5) right ventricular failure secondary to pulmonary hypertension; 6) congestive heart failure (see WARNINGS) unless the failure is secondary to a tachyarrhythmia treatable with INDERAL; 7) in patients on adrenergic-augmenting psychotropic drugs (including MAO inhibitors), and during the two week withdrawal period from such drugs.

WARNINGS

CARDIAC FAILURE: Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure, and inhibition with beta-blockade always carries the potential hazard of further depressing myocardial contractility and precipitating cardiac failure. INDERAL acts selectively without abolishing the inotropic action of digitalis on the heart muscle (*i.e.*, that of supporting the strength of myocardial contractions). In patients already receiving digitalis, the positive inotropic action of digitalis may be reduced by INDERAL's negative inotropic effect. The effects of INDERAL and digitalis are additive in depressing AV conduction.

IN PATIENTS WITHOUT A HISTORY OF CARDIAC FAILURE, continued depression of the myocardium over a period of time can, in some cases, lead to cardiac failure. In rare instances, this has been observed during INDERAL therapy. Therefore, at the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or given a diuretic, and the response observed closely: a) if cardiac failure continues, despite adequate digitalization and diuretic therapy, INDERAL therapy should be immediately withdrawn; b) if tachyarrhythmia is being controlled, patients should be maintained on combined therapy and the patient closely followed until threat of cardiac failure is over.

IN PATIENTS WITH ANGINA PECTORIS, there have been reports of exacerbation of angina and, in some cases, myocardial infarction, following *abrupt* discontinuation of INDERAL therapy. Therefore, when discontinuance of INDERAL is planned the dosage should be gradually reduced and the patient carefully monitored. In addition, when INDERAL is prescribed for angina pectoris, the patient should be cautioned against interruption or cessation of therapy without the physician's advice. If INDERAL therapy is interrupted and exacerbation of angina occurs, it usually is advisable to reinstitute INDERAL therapy and take other measures appropriate for the management of unstable angina pectoris. Since coronary artery disease may be unrecognized, it may be prudent to follow the above advice in patients considered at risk of having occult atherosclerotic heart disease, who are given propranolol for other indications.

IN PATIENTS WITH THYROTOXICOSIS, possible deleterious effects from long term use have not been adequately appraised. Special consideration should be given to propranolol's potential for aggravating congestive heart failure. Propranolol may mask the clinical signs of developing or continuing hyperthyroidism or complications and give a false impression of improvement. Therefore, abrupt withdrawal of propranolol may be followed by an exacerbation of symptoms of hyperthyroidism, including thyroid storm. This is another reason for withdrawing propranolol slowly. Propranolol does not distort thyroid function tests.

IN PATIENTS WITH WOLFF-PARKINSON-WHITE SYNDROME, several cases have been reported in which, after propranolol, the tachycardia was replaced by a severe bradycardia requiring a demand pacemaker. In one case this resulted after an initial dose of 5 mg propranolol.

IN PATIENTS DURING ANESTHESIA with agents that require catecholamine release for maintenance of adequate cardiac function, beta blockade will impair the desired inotropic effect. Therefore, INDERAL should be titrated carefully when administered for arrhythmias occurring during anesthesia.

IN PATIENTS UNDERGOING MAJOR SURGERY, beta blockade impairs the ability of the heart to respond to reflex stimuli. For this reason, with the exception of pheochromocytoma, INDERAL should be withdrawn 48 hours prior to surgery, at which time all chemical and physiologic effects are gone according to available evidence. However, in case of emergency surgery, since INDERAL is a competitive inhibitor of beta receptor agonists, its effects can be reversed by administration of such agents, *e.g.*, isoproterenol or levarterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has also been reported.

IN PATIENTS PRONE TO NONALLERGIC BRONCHOSPASM (*e.g.*, CHRONIC BRONCHITIS, EMPHYSEMA), INDERAL should be administered with caution since it may block bronchodilation produced by endogenous and exogenous catecholamine stimulation of beta receptors.

DIABETICS AND PATIENTS SUBJECT TO HYPOGLYCEMIA: Because of its beta-adrenergic blocking activity, INDERAL may prevent the appearance of premonitory signs and symptoms (pulse rate and pressure changes) of acute hypoglycemia. This is especially important to keep in mind in patients with labile diabetes. Hypoglycemic attacks may be accompanied by a precipitous elevation of blood pressure.

USE IN PREGNANCY: The safe use of INDERAL in human pregnancy has not been established. Use of any drug in pregnancy or women of childbearing potential requires that the possible risk to mother and/or fetus be weighed against the expected therapeutic benefit. Embryotoxic effects have been seen in animal studies at doses about 10 times the maximum recommended human dose.

PRECAUTIONS

Patients receiving catecholamine depleting drugs such as reserpine should be closely observed if INDERAL is administered. The added catecholamine blocking action of this drug may then produce an excessive reduction of the resting sympathetic nervous activity. Occasionally, the pharmacologic activity of INDERAL may produce hypotension and/or marked bradycardia resulting in vertigo, syncopal attacks, or orthostatic hypotension.

As with any new drug given over prolonged periods, laboratory parameters should be observed at regular intervals. The drug should be used with caution in patients with impaired renal or hepatic function.

ADVERSE REACTIONS

Cardiovascular: bradycardia; congestive heart failure; intensification of AV block; hypotension; paresthesia of hands; arterial insufficiency, usually of the Raynaud type; thrombocytopenic purpura

Central Nervous System: lightheadedness; mental depression manifested by insomnia, lassitude, weakness, fatigue; reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics

Gastrointestinal: nausea, vomiting, epigastric distress, abdominal cramping, diarrhea, constipation, mesenteric arterial thrombosis, ischemic colitis

Allergic: pharyngitis and agranulocytosis, erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress

Respiratory: bronchospasm

Hematologic: agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura

Miscellaneous: reversible alopecia. Oculomucocutaneous reactions involving the skin, serous membranes and conjunctivae reported for a beta blocker (practolol) have not been conclusively associated with propranolol.

Clinical Laboratory Test Findings: Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase

DOSAGE AND ADMINISTRATION

ORAL

HYPERTENSION—*Dosage must be individualized.* The usual initial dosage is 40 mg INDERAL twice daily, whether used alone or added to a diuretic. Dosage may be increased gradually until adequate blood pressure is achieved. The usual dosage is 160 to 480 mg per day. In some instances a dosage of 640 mg may be required. The time needed for full hypertensive response to a given dosage is variable and may range from a few days to several weeks.

While twice-daily dosing is effective and can maintain a reduction in blood pressure throughout the day, some patients, especially when lower doses are used, may experience a modest rise in blood pressure toward the end of the 12 hour dosing interval. This can be evaluated by measuring blood pressure near the end of the dosing interval to determine whether satisfactory control is being maintained throughout the day. If control is not adequate, a larger dose, or 3 times daily therapy may achieve better control.

PEDIATRIC DOSAGE

At this time the data on the use of the drug in this age group are too limited to permit adequate directions for use.

INTRAVENOUS

The intravenous administration of INDERAL has not been evaluated adequately in the management of hypertensive emergencies.

OVERDOSAGE OR EXAGGERATED RESPONSE

IN THE EVENT OF OVERDOSAGE OR EXAGGERATED RESPONSE, THE FOLLOWING MEASURES SHOULD BE EMPLOYED:

BRADYCARDIA—ADMINISTER ATROPINE (0.25 to 1.0 mg). IF THERE IS NO RESPONSE TO VAGAL BLOCKADE, ADMINISTER ISOPROTERENOL CAUTIOUSLY.

CARDIAC FAILURE—DIGITALIZATION AND DIURETICS.

HYPOTENSION—VASOPRESSORS, *e.g.*, LEVARTERENOL OR EPINEPHRINE (THERE IS EVIDENCE THAT EPINEPHRINE IS THE DRUG OF CHOICE).

BRONCHOSPASM—ADMINISTER ISOPROTERENOL AND AMINOPHYLLINE.

HOW SUPPLIED

INDERAL (propranolol hydrochloride)

TABLETS

No. 461—Each scored tablet contains 10 mg of propranolol hydrochloride, in bottles of 100 and 1,000. Also in unit dose package of 100.

No. 462—Each scored tablet contains 20 mg of propranolol hydrochloride, in bottles of 100 and 1,000. Also in unit dose package of 100.

No. 464—Each scored tablet contains 40 mg of propranolol hydrochloride, in bottles of 100 and 1,000. Also in unit dose package of 100.

No. 468—Each scored tablet contains 80 mg of propranolol hydrochloride, in bottles of 100 and 1,000. Also in unit dose package of 100.

INJECTABLE

No. 3265—Each ml contains 1 mg of propranolol hydrochloride in Water for Injection. The pH is adjusted with citric acid. Supplied as: 1 ml ampuls in boxes of 10.

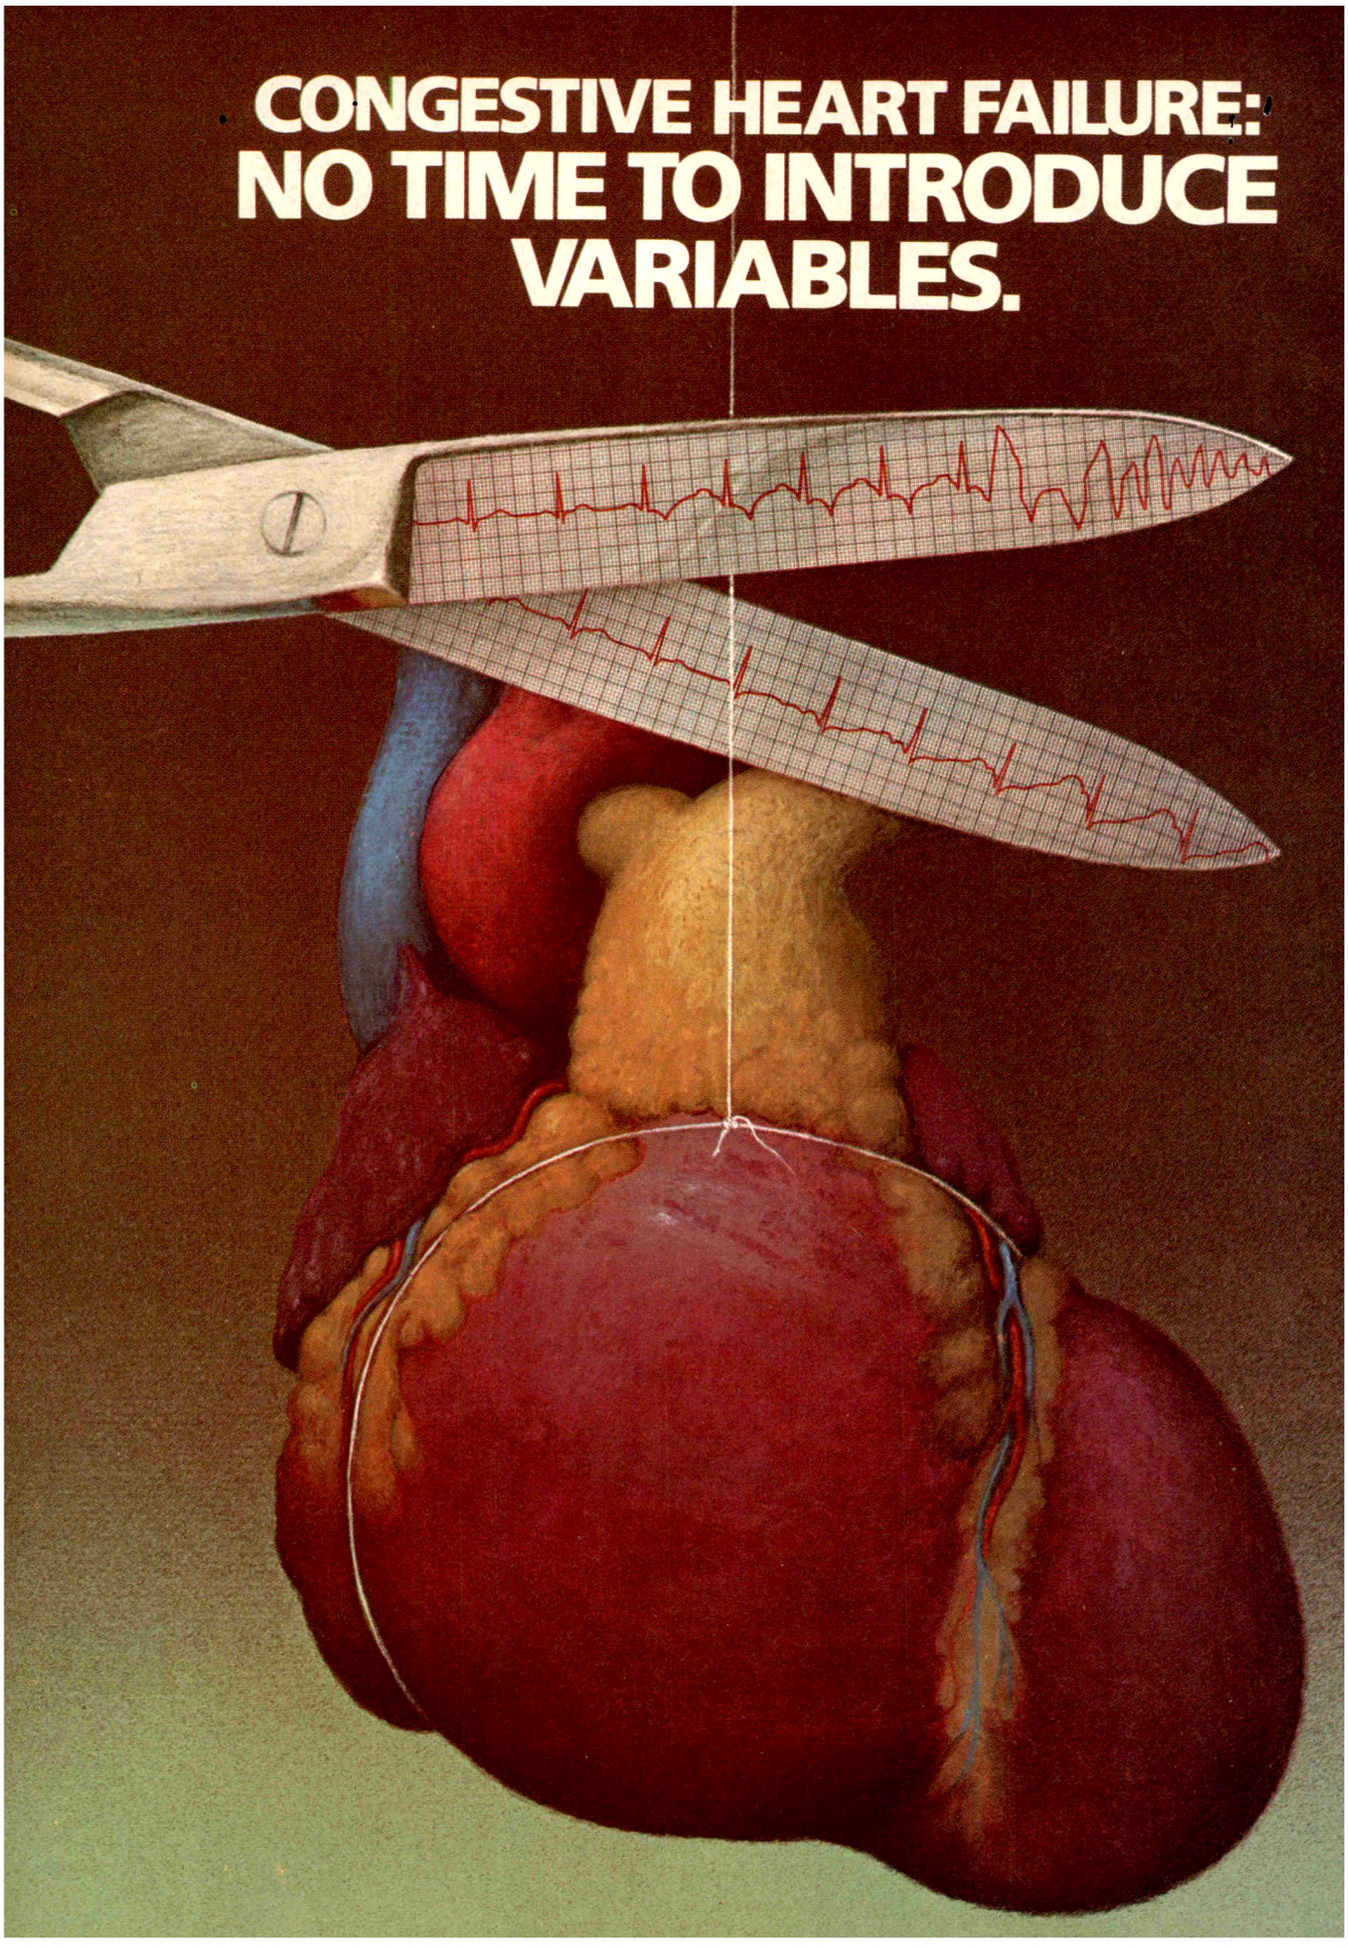
CONGESTIVE HEART FAILURE: NO TIME TO INTRODUCE VARIABLES.



If you wouldn't think of changing your brand of digitalis, shouldn't you think twice before switching from LASIX® furosemide to a substitute?

BRAND OF

Both digitalis and diuretics are almost always used in congestive heart failure. But both can cause serious cardiac arrhythmias.[1] *Digitalis, because digitalization is one of the most precarious titrations in all of medicine. And diuretics, because diuretic-induced hypokalemia increases the vulnerability to digitalis toxicity.*[2] *See warnings and precautions in the brief summary of product information on the next page.*

In serious congestive heart failure, the diuretic most frequently administered with digitalis is LASIX® brand of furosemide. However, the bioavailability of furosemide may be significantly altered by a change in tablet disintegrants and/or excipients.[3,4,5] And variations in the bioavailability of unlawfully-marketed furosemide tablets have produced unpredictable and serious clinical effects.[6]

Therefore, once the patient is stabilized on digitalis and LASIX®, changes in his cardiac regimen should be minimized.

LASIX®—the diuretic with the best record of success in all degrees of congestive heart failure.

LASIX® is the original brand of furosemide. It is LASIX® that established the standard for furosemide performance. It is LASIX® that is the subject of almost 6,000 published papers. It is LASIX® that has been used successfully in millions of digitalized patients over the past 14 years. And it is LASIX® that has a remarkable quality-control record—almost 8 billion tablets manufactured without a single product recall.

LASIX® tablets are available in a dosage strength to meet almost every patient need—20, 40 and 80 mg.

Before prescribing, please consult complete product information, a summary of which appears on the following page.

IN CONGESTIVE HEART FAILURE.

LASIX®
FUROSEMIDE

ONE LESS VARIABLE IN THE DIGITALIZED PATIENT

Lasix® (furosemide)

A brief summary of the Prescribing Information for Lasix (furosemide). Tablets 20, 40 and 80 mg.

WARNING: Lasix (furosemide) is a potent diuretic which, if given in excessive amounts, can lead to a profound diuresis with water and electrolyte depletion. Therefore, careful medical supervision is required, and dose and dose schedule have to be adjusted to the individual patient's needs.

INDICATIONS: Edema associated with congestive heart failure, cirrhosis of the liver, and renal disease, including the nephrotic syndrome. Hypertension when used alone or in combination with other antihypertensive drugs; patients not adequately controlled with thiazides also probably will not be adequately controlled with furosemide alone.

CONTRAINDICATIONS: Because animal reproductive studies have shown that furosemide may cause fetal abnormalities, the drug is contraindicated in women of childbearing potential. Anuria. History of hypersensitivity to the compound.

WARNINGS: Excessive diuresis may result in dehydration and reduction in blood volume, with circulatory collapse and with the possibility of vascular thrombosis and embolism, particularly in elderly patients. Excessive loss of potassium in patients receiving digitalis glycosides may precipitate digitalis toxicity. Exercise care in patients receiving potassium-depleting steroids. Perform frequent serum electrolyte, CO_2, and BUN determinations during first few months of therapy and periodically thereafter; and correct abnormalities or temporarily withdraw the drug. Initial therapy of patients with hepatic cirrhosis and ascites is best carried out in the hospital. Closely observe cirrhotic patients for sudden fluid and electrolyte imbalances that may precipitate hepatic coma. Supplemental potassium chloride and, if required, an aldosterone antagonist are helpful in preventing hypokalemia and metabolic alkalosis. Discontinue furosemide if increasing azotemia and oliguria occur during treatment of severe, progressive renal disease. Observe patients regularly for possible blood dyscrasias, liver damage, or other idiosyncratic reactions. Patients with known sulfonamide sensitivity may show allergic reactions. Furosemide may potentiate the therapeutic effect of other antihypertensive agents. Potentiation occurs with ganglionic or peripheral adrenergic blocking drugs. Exacerbation or activation of systemic lupus erythematosus may occur. Furosemide appears in breast milk. If use of the drug is essential, the patient should stop nursing. Cases of tinnitus and reversible hearing impairment have been reported.

There have also been some reports of cases in which irreversible hearing impairment occurred. Usually ototoxicity has been reported when furosemide was injected rapidly in patients with severe impairment of renal function at doses exceeding several times the usual recommended dose and in whom other drugs known to be ototoxic were given. If the physician elects to use high-dose parenteral therapy in patients with severely impaired renal function, controlled intravenous infusion is advisable. (For adults, an infusion rate not exceeding 4 mg furosemide per minute has been used.)

PRECAUTIONS: As with any effective diuretic, electrolyte depletion may occur, especially in patients receiving higher doses and a restricted salt intake. Patients receiving furosemide should be observed for clinical signs of fluid or electrolyte imbalance, namely, hyponatremia, hypochloremic alkalosis, and hypokalemia. Serum and urine electrolyte determinations are particularly important when the patient is vomiting excessively or receiving parenteral fluids. Medication such as digitalis may also influence serum electrolytes. Hypokalemia may develop with furosemide as with any other potent diuretic, especially with brisk diuresis, when cirrhosis is present, or during concomitant use of corticosteroids or ACTH. Interference with adequate oral electrolyte intake will also contribute to hypokalemia. Digitalis may exaggerate metabolic effects of hypokalemia, especially with reference to myocardial activity. Asymptomatic hyperuricemia can occur and gout may rarely be precipitated. Increases in blood glucose and alterations in glucose tolerance tests with abnormalities of the fasting and two-hour postprandial sugar have been observed, and rare cases of precipitation of diabetes mellitus have been reported. Furosemide may lower serum calcium levels, and rare cases of tetany have been reported. Periodic serum calcium levels should be obtained. Reversible elevations of BUN may be seen. These have been observed in association with dehydration, which should be avoided, particularly in patients with renal insufficiency. Patients receiving high doses of salicylates in conjunction with furosemide may experience salicylate toxicity at lower doses because of competitive renal excretory sites. Furosemide has a tendency to antagonize the effects of tubocurarine and may potentiate the action of succinylcholine. Lithium generally should not be given with diuretics because they reduce its renal clearance and add a high risk of lithium toxicity. Diuretics such as furosemide may enhance the nephrotoxicity of cephaloridine. Therefore, furosemide and cephaloridine should not be administered simultaneously. Furosemide may decrease arterial responsiveness to norepinephrine. This diminution is not sufficient to preclude effectiveness of the pressor agent for therapeutic use.

It has been reported in the literature that coadministration of indomethacin may reduce the natriuretic and antihypertensive effects of Lasix (furosemide) in some patients. This effect has been attributed to inhibition of prostaglandin synthesis by indomethacin. Indomethacin may also affect plasma renin levels and aldosterone excretion; this should be borne in mind when a renin profile is evaluated in hypertensive patients. Patients receiving both indomethacin and Lasix (furosemide) should be observed closely to determine if the desired diuretic and/or antihypertensive effect of Lasix (furosemide) is achieved.

ADVERSE REACTIONS: Anorexia, oral and gastric irritation, nausea, vomiting, cramping, diarrhea, constipation, jaundice (intrahepatic jaundice), pancreatitis, dizziness, vertigo, paresthesias, headache, xanthopsia, blurred vision, tinnitus and hearing loss, anemia, leukopenia, agranulocytosis (rare), thrombocytopenia, aplastic anemia (rare), purpura, photosensitivity, rash, urticaria, necrotizing angiitis (vasculitis, cutaneous vasculitis), exfoliative dermatitis, erythema multiforme, pruritus. Orthostatic hypotension may occur and may be exaggerated by alcohol, barbiturates, or narcotics. Other adverse reactions include hyperglycemia, glycosuria, hyperuricemia, muscle spasm, weakness, restlessness, urinary bladder spasm, thrombophlebitis.

Q66190-380

Announcing the comprehensive study of...the most fascinating syndrome in Cardiology...

THE PRE-EXCITATION SYNDROME: FACTS AND THEORIES

Libi Sherf, MD, FACC

Assoc. Professor of Cardiology, Heart Institute, Chaim Sheba Medical Center, Tel Hashomer, University of Tel Aviv—Sackler School of Medicine, and Visiting Assoc. Professor, Dept. of Medicine, University of Alabama.

Henry N. Neufeld, MD, FACC

Professor of Medicine and Chaim Sheba Professor of Cardiology, Chief, Heart Institute, Chaim Sheba Medical Center, Tel Hashomer, University of Tel Aviv—Sackler School of Medicine.

Every cardiologist, internist, pediatrician, surgeon—indeed, *every physician*—should have a good basic knowledge of the Pre-excitation Syndrome. Here are just a few reasons why this is so essential:

- ☐ ⅓ of all pre-excitation cases are misdiagnosed.
- ☐ 5% to 10% of all tachycardias in adults are produced by pre-excitation.
- ☐ In ½ of all infants under 10 months of age with life-threatening tachycardias, the tachycardias are actually secondary to pre-excitation.
- ☐ ⅓ to ½ of all children with pre-excitation have an additional heart disease.

Starting with Wolff, Parkinson and White's classic paper, this book gives a comprehensive summary of all important facts of pre-excitation, plus the authors' personal experiences of follow-up studies of patients through many decades. It also brings a broad view of the literature and discusses the different structural and physiological aspects which form the pathomechanism of pre-excitation.

"What is offered richly in this book is a methodical and comprehensive analysis of virtually all currently available knowledge on the subject. This is done with an admirable even-handedness, dealing objectively with all viewpoints but at the same time evaluating relative strengths and weaknesses of each observation and hypothesis. There is brought a wisdom here which only time and experience can provide. The encyclopedic references alone would make the book invaluable to anyone seriously interested in the Wolff-Parkinson-White syndrome. But when knowledgeable discussion and personal observations are added, it is genuinely a monumental contribution to clinical cardiology and cardiac electrophysiology."

Thomas N. James, MD
The Mary Gertrude Waters Professor of Cardiology and Chairman of the Department of Medicine, The University of Alabama in Birmingham, and Physician-in-Chief, University of Alabama Hospitals.

New 2nd Edition!
THE DISORDERS OF CARDIAC RHYTHM
By **Leo Schamroth,** M.D.(Rand.), D.Sc., F.R.C.P.(Edin.), F.R.C.P.(Glasg.), F.A.C.C., F.R.S.(S.Af.)

Since publication of the previous edition, there has been an avalanche of increasingly sophisticated techniques in electrocardiology and electrophysiology. This new 2nd edition has now been expanded to a comprehensive 900-page, two-volume set which includes many new chapters, a total of 222 case studies, and a substantial amount of new material. Among other important subjects, this edition offers the latest information on:

- His bundle electrography
- sick sinus syndrome
- A-V junctional tachycardias
- bradycardia-dependent block

No matter what your degree of expertise, you'll want to own a copy of this outstanding two-volume set packaged in an attractive library slip case. It is the most comprehensive and authoritative work on the subject in print!
1980. 900 pages, 449 illustrations. Price, $175.00.

DyNA MO–
ALL AROUND PERFORMANCE.

When we first introduced DynaMo, many chose it for its excellent mobility. At 1.5 mph (2.4 km/hr), it brought a complete diagnostic capability to the CCU, or to the most remote parts of the hospital.

Today, DynaMo is succeeding because of its performance in any situation. DynaMo delivers incomparable resolution in the nuclear medicine department or out of it. Our integral Micro Z™ Processor gives it automatic image correction and up to 15% improvement in resolution. With its own lightweight collimators and its unique five-motion detector, it's easy to operate, even in crowded situations. And DynaMo interfaces with any nuclear medicine computer.

Whether you choose it as a prime unit, an all-around second camera, or as a complete department unto itself, you'll find DynaMo stands alone.

For more information, call your Picker representative or write Picker Corporation, 12 Clintonville Road, Northford, CT 06472, or Picker International, 595 Miner Road, Highland Hts., OH 44143.

WE'LL DO MORE FOR YOU.

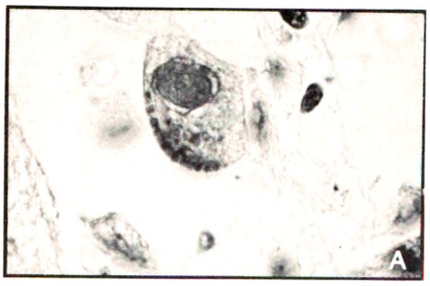
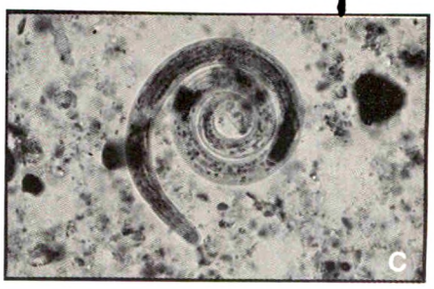
Paintings by Jackson Pollock?





Good guess for a layman. But *to you* these are the enemy. They are Cytomegalovirus gastritis (A) Disseminated coccidioidomycosis(B) and Strongyloides stercoralis filariform larva (C) . . . infections which demand special care when they strike patients with pre-existing illnesses and deficiencies. They are among the many discussed in . . .

INFECTIONS
IN THE ABNORMAL HOST

Edited by Michael H. Grieco, M.D.
Text by 47 Specialists. Illustrated with 147 Drawings and Photos, 78 in Full Color

Now at your fingertips . . . for instant reference . . . for rewarding study . . . the knowledge of world-renowned specialists to help you understand, diagnose, and manage infections which attack patients under treatment for

- Diabetes
- Alcoholism
- Cancer
- Drug Addiction
- Rheumatic Disease
- Uremia
- Pulmonary Disease
- Hepatic Insufficiency
- Allograft Transplantation, etc., etc.

Infections in the Abnormal Host brings together in one giant encyclopedic volume, over 1,000 pages, the guidance of a specialist team whose collaboration began in the 1960's. In 36 revealing chapters they review the mechanics of host defenses . . .the various underlying disorders and the latest treatments by chemotherapy, management of agranulocytosis, immunological reconstitution, passive and active immunotherapy, and immunostimulation.

A detailed indexing system gives you instant access to every diagnostic procedure, every treatment in the book. Study the entire book and you will gain priceless knowledge of an important and complex field. Consult it as the need arises, and it will help you understand, diagnose, and manage the many infections which strike patients whose defense mechanisms are down.

Check this list of chapters

PART I HOST DEFENSES

• Introduction to the Abnormal Host and Complicating Infections • The Neutrophil in Host Defense: Congenital, Acquired and Drug-induced Abnormalities • The Complement System in Human Disease • Structure and Function of Immunoglobulins • Human Lymphocyte Subpopulations: Surface, Intracellular, Enzymatic Markers and Functions • Congenital and Acquired Primary Disorders of B and T Lymphocyte Function • Drug-induced B and T Lymphocyte and Monocyte Dysfunction • Cutaneous, Pulmonary, Gastrointestinal and Genitourinary Defense Mechanisms and Relationship to Nosocomial Infections • The Effects of Malnutrition on Host Responses and the Metabolic Sequelae of Infections • Humoral and Cellular Responses to Infection

PART II INFECTIONS ASSOCIATED WITH THE ABNORMAL HOST

• Pyogenic Bacterial Infections • Higher Bacterial and Fungal Infections • Mycobacterial Infections • Viral and Chlamydial Infections • Protozoal and Helminthic Infections • Infections Complicating the Transfusion of Blood, Blood Products, Animal Exposure and Animal Products • Infections Complicating the Alcoholic Host • Infections in Parenteral Narcotic and Drug Abusers • Infections Complicating Uremia and Organ Transplantation • Infections in Patients with Neoplastic Diseases • Infections Complicating Diabetes Mellitus • Diagnosis and Treatment of Diffuse Pneumonias • Host Deficiency States and Central Nervous System Infections • Genitourinary Infections • Infections Complicating the Rheumatic Diseases • Endovascular and Prosthetic Implant Infections • Intraocular Manifestations of Systemic Infections • Selected Histopathologic Responses • The Microbiology Laboratory in Diagnosis and Therapy • Infections Complicating Surgical or Functional Splenectomy and Gastrectomy

PART III MANAGEMENT

• Antimicrobial Therapy in the Compromised Host: Resistance, Pharmacology and Toxicity • Chemotherapy for Viral and Chlamydial Infections • Chemotherapy for Protozoal and Helminthic Infections • Infection Prevention in Patients with Cancer and Granulocytopenia • Immunologic Reconstitution • Gamma Globulin and Vaccine Therapy

• Index

Accuracy of Systolic Time Intervals in Detecting Abnormal Left Ventricular Performance in Coronary Artery Disease

RICHARD S. STACK, MD
YOUNG H. SOHN, MD
ARNOLD M. WEISSLER, MD, FACC

Detroit, Michigan

Sixty-six consecutive patients with a history of previous myocardial infarction and 48 patients with angina pectoris without evidence of previous myocardial infarction, all of whom had diagnostic coronary arteriography and left ventriculography, were studied in a prospective analysis of the accuracy of noninvasively determined systolic time intervals as a measure of global left ventricular performance. Forty-one patients who were evaluated for atypical chest pain and found to have normal coronary arteries and left ventricular performance served as control subjects. Six methods of statistical analysis were employed in assessing the accuracy of systolic time intervals in relation to the left ventricular ejection fraction: (1) analysis of variance, (2) cumulative distribution analysis, (3) correlation, (4) sensitivity and specificity, (5) percent agreement, and (6) logistic regression analysis. These tests permitted comparison between the systolic time intervals and the angiographic left ventricular ejection fraction. Analysis of variance revealed identical discriminating power for the ratio of the preejection period to left ventricular ejection time (PEP/LVET) and left ventricular ejection fraction in separating the normal group and patients without previous myocardial infarction from the patients with previous myocardial infarction. The preejection period and left ventricular ejection time corrected for heart rate were less discriminating than left ventricular ejection fraction or PEP/LVET. The cumulative distribution plots for the left ventricular ejection fraction and PEP/LVET in the three groups of patients were remarkably similar. The correlation of PEP/LVET and left ventricular ejection fraction for all three groups of patients was 0.84. The sensitivity and specificity of the PEP/LVET in relation to the left ventricular ejection fraction were 88 and 96 percent, respectively. The overall agreement between the two measures in detecting the prevalence of abnormality in global left ventricular performance in subgroups of patients was 92 percent. By logistic regression analysis the two measures had equal capacity in discriminating the patients with previous myocardial infarction from the control group.

The multiple strategies of comparison employed in this study document the close relation of measures of the timing of the left ventricular contraction cycle by systolic time intervals and estimates of the extent of left ventricular contraction by ejection fraction in patients with coronary artery disease. It is concluded that these measures afford independent and complementary methods of defining the presence of abnormal left ventricular performance in the resting supine patient with coronary artery disease.

From the Department of Medicine, Wayne State University School of Medicine, Harper-Grace Hospitals, Detroit, Michigan. Manuscript received July 24, 1979; revised manuscript received October 6, 1980, accepted November 6, 1980.

Systolic time intervals have been shown to be useful noninvasive measures of global left ventricular performance in various disease states.[1–5] However, there has been some controversy regarding the accuracy of systolic time intervals in patients with coronary artery disease. Some investigators[6–9] have been unable to demonstrate a close correlation between systolic time intervals derived with various methods and other established clinical measures of left ventricular performance. Other

studies[10] have found a remarkably high incidence rate of abnormal systolic time interval measurements in asymptomatic patients with stable coronary artery disease who had no overt clinical evidence of cardiac dysfunction on history or physical examination. These findings led to the following questions: Are systolic time intervals capable of discriminating between normal and abnormal left ventricular performance in a large group of patients with coronary artery disease and, if so, are the findings of abnormality by systolic time intervals clinically pertinent? The current prospective study on the accuracy of systolic time intervals was designed to answer these questions.

Methods

Study patients: Sixty-six consecutive patients who had a history of myocardial infarction and who were referred to our hemodynamics laboratory for evaluation of angina pectoris (Group II) and 48 consecutive patients who were admitted for coronary angiographic studies because of clinically evident angina pectoris and who had no evidence of previous myocardial infarction (Group III) were studied. All patients with myocardial infarction had recovered from the acute episode, which occurred at least 3 months before this study. Documentation of the infarction was established by (1) typical history of precordial chest discomfort, (2) characteristic serum enzyme changes, and (3) sequential evolution of electrocardiographic changes with persistence of pathologic Q waves. The patients without previous infarction had no history of prolonged precordial discomfort nor any electrocardiographic evidence of infarction. Both groups of patients with coronary artery disease were demonstrated to have 50 percent or greater narrowing of the diameter of at least one major coronary artery on coronary angiography. Forty-one patients who were referred for diagnosis of atypical precordial chest discomfort and who were later found to have normal coronary arterial and ventriculographic studies at cardiac catheterization (Group I) were used as control subjects.

Cardiac catheterization: Left ventricular end-diastolic pressure was obtained using retrograde catheterization of the left ventricle with a fluid-filled catheter system attached to a Statham P23Db pressure transducer. Left ventriculography was performed in the right anterior oblique position with 35 mm film at 30 frames/s utilizing a 9 inch (22.9 cm) image intensifier system with automated injection of Renovist® II (29 percent diatrizoate sodium and 28.5 percent diatrizoate meglumine). Left ventricular end-diastolic and end-systolic volumes were measured in the right anterior oblique position with the method of Green et al.[11] The ejection fraction was then calculated as the end-diastolic volume minus the end-systolic volume divided by the end-diastolic volume.[12,13] The ejection fraction determined in this manner by the single plane method is the most commonly employed clinical standard for detecting normal and abnormal resting supine left ventricular performance in patients with coronary artery disease. Selective coronary cinearteriography was performed in the right and left anterior oblique positions using either the Sones or Judkins technique with manual injection of Renografin®-76 (10 percent diatrizoate sodium and 66 percent diatrizoate meglumine) at 60 frames/s.

Systolic time intervals: These intervals were measured as previously described using simultaneous electrocardiographic, phonocardiographic and carotid arterial pulse tracings recorded photographically at 100 mm/s with an Electronics for Medicine VR-6 system.[1,2] For the electrocardiographic recording the lead most clearly delineating the onset of ventricular depolarization was used. For the phonocardiographic recording a contact microphone (EFM model, PSA 23, 1.5 cm disk) was placed over the upper portion of the precordium in the optimal position for recording the initial high frequency vibrations of the second heart sound. A frequency band of 100 to 500 hertz was used for this purpose. The carotid arterial pulsation was recorded using a funnel-shaped pickup (diameter 2.3 cm) connected by a short length of polyethylene tubing (length 8 cm, internal diameter 2 mm) to a Statham P23Db strain gauge.

Two phases of the cardiac cycle were measured directly: total electromechanical systole ($Q\text{-}S_2$) and left ventricular ejection time (LVET). The $Q\text{-}S_2$ interval was measured from the onset of ventricular depolarization on the electrocardiogram to the beginning of the initial high frequency component of the second heart sound in the phonocardiogram. The LVET was measured from the beginning of the upstroke to the trough of the incisural notch of the carotid arterial pulse tracing. The left ventricular preejection period was derived by subtracting left ventricular ejection time from the $Q\text{-}S_2$ interval. All intervals were calculated as the mean of measurements from 10 consecutive beats, each read to the nearest 5 ms. Left ventricular ejection time and preejection period measurement were corrected for heart rate using previously reported linear regression equations and were expressed as their respective indexes.[1,2,4] The ratio of PEP/LVET was calculated using the uncorrected values for prejection period and left ventricular ejection time.

Statistical analysis: This was performed with the aid of an IBM 370/165 computer located at Triangle Universities Computation Center, Research Triangle Park, North Carolina. Six methods of statistical analysis were employed in assessing the accuracy of the systolic time intervals in relation to the ejection fraction: (1) Kruskal-Wallis analysis of variance, (2) cumulative distribution analysis, (3) Pearson product-moment correlation, (4) sensitivity and specificity, (5) percent agreement, and (6) logistic regression analysis. These tests where chosen because they allow direct comparison of the systolic time intervals with the angiographic ejection fraction in characterizing left ventricular performance in both normal and abnormal populations of patients. Second, these methods are distribution-free and do not depend on a Gaussian distribution for the statistical validity of the comparisons. The use of parametric tests in non-normally distributed populations can lead to significant errors in interpretation of results.[14,15] The Kruskal-Wallis nonparametric analysis of variance procedure allows one to test for differences in the distribution of the systolic time intervals and ejection fraction among patient groups. The cumulative distribution plot allows a direct visual impression of the distribution of all data in each group. The ability of each test of ventricular performance to characterize the normal and abnormal populations can thus be readily appreciated. The Pearson correlation indicates the strength of the association between the systolic time interval and ejection fraction measurements among all patients. The sensitivity, specificity and percent agreement allow one to compare the systolic time intervals with the ejection fraction, assuming that the angiographically determined ejection fraction is able to categorize patients correctly as having either normal or abnormal left ventricular performance. The sensitivity as applied to the systolic time intervals is defined as the percent of abnormal patients (by ejection fraction) detected correctly, while the specificity is defined as the percent of normal patients correctly identified. The percent agreement is simply the number of patients with concordant abnormality by both tests plus the number of

* Comparison of group data by analysis of variance.

CAD = coronary artery disease; LVEF = left ventricular ejection fraction; LVET = left ventricular ejection time; LVETI = left ventricular ejection time index; MED = median; MI = myocardial infarction; p = probability; PEP = preejection period; PEPI = preejection period index; Q = quartile; SD = standard deviation.

patients with concordant normality divided by the total number of patients expressed in percent. The logistic regression analysis allows comparison of the ability of ejection fraction and systolic time intervals to separate independently normal patients from those with previous myocardial infarction on the basis of left ventricular performance alone.

It should be emphasized that a prospective approach was used in selecting patients for study. Consecutive patients referred to the hemodynamics laboratory for catheterization had noninvasive evaluation within 48 hours of catheterization. The measurement of the systolic time intervals and ejection fraction was made independently and in separate laboratories by different workers, each uninformed of the corresponding data in the other laboratory.

Results

PEP/LVET versus ejection fraction: The mean, median and quartile data for left ventricular ejection fraction (LVEF), PEP/LVET, preejection period index (PEPI) and left ventricular ejection time index (LVETI) for all three groups of patients (control [Group I], coronary artery disease without myocardial infarction [Group II] and coronary artery disease with myocardial infarction [Group III]) are summarized in Table I. A curve-fitting technique was used to compare the distribution of the data in each of the groups to an ideal Gaussian distribution. The data for both PEP/LVET and ejection fraction in the 41 normal subjects were shown to have a Gaussian distribution so that the normal range for both variables was taken as the mean ± 2 standard deviations. Thus the upper limit of normal for PEP/LVET was 0.42, and the lower limit of normal for the angiographic ejection fraction was 53 percent. These data correspond to previously established norms for each variable.[1,11] The distribution of the data among patients with previous myocardial infarction, however, was significantly different from a Gaussian distribution for both ejection fraction ($p = 0.01$) and PEP/LVET ($p = 0.04$). Thus all further statistical comparisons utilized distribution-free nonparametric analysis.

The last three columns in Table I show the chi-square and probability (p) values for all variables using the Kruskal-Wallis nonparametric analysis of variance. The chi-square values for the comparison of the normal group to the patients with coronary artery disease but without infarction were quite small, demonstrating the absence of a significant difference in left ventricular performance in the two groups. The chi-square values for the comparison between the normal group and the patients with coronary artery disease and previous infarction were large and highly significant for all variables. It is of interest to note that the chi-square values for ejection fraction and PEP/LVET were close in magnitude (42.5 and 42.9, respectively), demonstrating a similar discriminating power in separating the normal patients from those with previous infarction. The preejection period and left ventricular ejection time indexes were also able to separate these groups but had lower chi-square values, indicating a somewhat lower discriminating capacity for distinguishing left ventricular dysfunction in patients with chronic coronary artery disease.

Cumulative distribution plots of the ejection fraction for each of the three groups are shown in Figure 1, and corresponding plots of PEP/LVET appear in Figure 2. The characterization of the left ventricular performance of each group by the ejection fraction was remarkably similar to that shown by the PEP/LVET. Patients with coronary artery disease without previous myocardial infarction appear very similar to the normal patients according to both variables, whereas the patients with previous infarction are quite distinct from the normal patients according to both PEP/LVET and ejection fraction. Thus, in the group comparisons, the invasive and noninvasive measures were very similar in the characterization of both the normal and the abnormal populations of patients.

The correlation of PEP/LVET and ejection fraction in all three groups of patients is shown in Figure 3. The

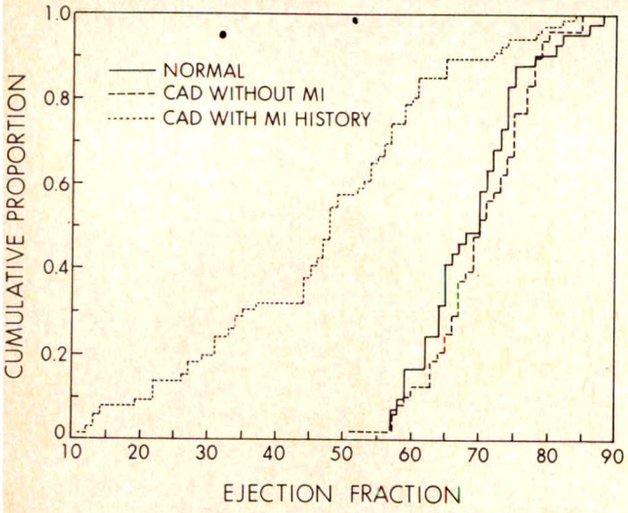

FIGURE 1. Cumulative distribution plot of the ejection fraction in the normal patients (**solid line**), those with coronary artery disease without myocardial infarction (CAD without MI) (**dashed line**) and those with coronary artery disease and previous myocardial infarction (CAD with MI history) (**dotted line**).

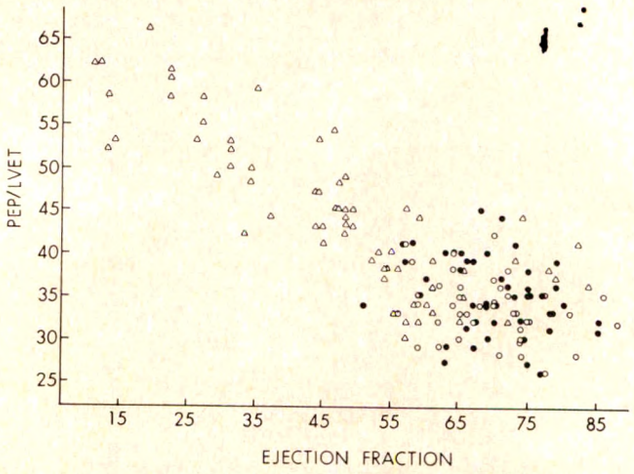

FIGURE 3. Correlation of PEP/LVET and ejection fraction in the normal patients (**open circles**), those with coronary artery disease without myocardial infarction (**closed circles**) and those with coronary artery disease and previous myocardial infarction (**open triangles**).

Pearson correlation coefficient was 0.84, demonstrating a high degree of correlation among the patients in all three groups.

Sensitivity and specificity of PEP/LVET: To approach the question of whether PEP/LVET could reliably separate patients with normal from those with abnormal left ventricular performance, we assumed temporarily that the angiographic ejection fraction could correctly separate patients with normal from those with abnormal left ventricular performance in all instances. We were then able to calculate the sensitivity and specificity of PEP/LVET for detecting abnormal and normal left ventricular performance, respectively (Fig. 4). The calculations were derived from the pooled data of control patients and both groups of patients with coronary artery disease using the 2 standard deviation limit of 0.42 for the PEP/LVET. The sensitivity (88 percent) and specificity (96 percent) confirm the accuracy of the PEP/LVET limit of 0.42 in detecting the presence of abnormal and normal left ventricular ejection fraction.

To test for the most clinically useful demarcation between normal and abnormal ventricular performance by PEP/LVET, the sensitivity and specificity over a large range of limits for PEP/LVET were determined (Fig. 5). It is apparent from the data display that the point of maximal combined sensitivity and specificity occurs at the crossover point of the sensitivity and specificity curves. This crossover corresponds almost exactly (0.41) to 2 standard deviations above the mean for PEP/LVET (0.42). At a limit of 0.45, the point of 100 percent specificity is reached. All patients with a normal angiographic ejection fraction had a PEP/LVET value below this point. Similarly, at a limit of 0.34 the point of 100 percent sensitivity is achieved. The data for all patients with an abnormal left ventricular ejection fraction were above this limit.

Prevalence of abnormality by both tests: As an additional test of the clinical applicability of the systolic time interval measurements compared with that of the ejection fraction, the prevalence of abnormality by both tests as well as the percent agreement between the two tests in detecting abnormal left ventricular performance in several clinical subsets of patients was determined. Table II summarizes the prevalence of abnormality and the degree of agreement between PEP/LVET and ejection fraction in subgroups designated according to degree of arterial obstruction on angiography (those with one, two and three vessel disease), the presence of

elevated end-diastolic pressure at cardiac catheterization and the presence or absence of previous infarction. A high degree of agreement between PEP/LVET and ejection fraction was demonstrated in these subgroups of patients with coronary artery disease.

Logistic regression analysis to discriminate between normal and abnormal populations: The final approach to the analysis of the accuracy of the systolic time intervals in separating normal from abnormal patients was the use of logistic regression analysis. In this procedure the ability of both tests to separate the patients who had had a documented previous myocardial infarction (Group II) from the normal (control, Group I) patients on the basis of left ventricular performance was examined. Although many patients have fully compensated ventricular performance after recovering from an infarction, it follows that a more sensitive test will be able to detect the more subtle degrees of residual functional impairement. Table III gives the chi-square and corresponding p values for the logistic regression analysis of PEP/LVET, ejection fraction, and PEP/LVET and ejection fraction combined, in discriminating between normal patients and those with previous infarction on the basis of left ventricular performance alone. When considered independently, both PEP/LVET and ejection fraction are able to discriminate between these groups. When both tests are combined and the results for each measure are adjusted for the effect of the other, both PEP/LVET and ejection fraction remain highly significant, indicating that each test contributes important independent information in discriminating between the normal and abnormal populations.

Discussion

The present study was designed to test the accuracy of systolic time intervals in detecting abnormal left ventricular performance in patients with stable coronary artery disease. The preejection period/left ventricular ejection time ratio (PEP/LVET) was compared with the angiographically determined left ventricular ejection fraction, the most commonly applied clinical laboratory standard for defining the presence of global left ventricular dysfunction. The study included a large number of patients with angiographically defined coronary artery disease, including patients with and

Abbreviations as in Table I.

without previous myocardial infarction and encompassing a wide range of left ventricular performance. The statistical analysis was extended beyond correlation, the only statistical method used in all previous studies, since the latter does not provide a critical test of the accuracy of the systolic time intervals in differentiating normal from abnormal populations. A prospective analysis of consecutive patients referred for evaluation of coronary artery disease was used. The invasive and noninvasive data were acquired in independent laboratories by different technicians who were unaware of the results of the corresponding measurements.

Close correlation of changes in PEP/LVET and ejection fraction: The PEP/LVET, the ratio of preejection to ejection phase duration, like the ejection fraction, provides a measure of global performance of the left ventricle. The closeness of the changes in the PEP/LVET and the ejection fraction summarized in this study demonstrates a unique parallelism in the alteration of the timing of the events of the cardiac cycle with the decrease in the extent of chamber contraction that accompanies left ventricular dysfunction in coronary artery disease. When considered in relation to the difference in the physiologic events reflected in these methods, one a measure of timing and the other a measure of the extent of chamber contraction, the two determinations must be considered complementary indexes of the left ventricular contractile dysfunction that accompanies coronary artery disease.

Limitations of previous correlative studies: Previous investigations[6–9] correlating systolic time intervals with left ventricular ejection fraction have not consistently demonstrated r values for the relation between PEP/LVET and ejection fraction as high as that reported previously from our laboratory[5] or in the present study. However, the methods used to measure the systolic intervals in those studies differ from that described in our original investigations on systolic time intervals.[1,2] Thus, in three of the studies[6,8,9] only five complexes were employed for measuring the intervals despite admonitions[1,2,4] that a larger number of consecutive beats (at least 10) should be measured to obtain acceptable accuracy in measuring systolic time intervals. Further, the use of crystal transducers[6,9] and a glycerin pellet[7] without verification of their frequency response or time constant could account for major variations in the measurements in these studies. In one study[7] a computer approach to measuring systolic time intervals was employed as well. The correlation between the computer- and hand-measured preejection period, the measurement that encompasses all four landmarks employed in the measurement of systolic time intervals, was 0.85. This level of correlation itself imposes a lower correlation between PEP/LVET and ejection fraction than can be derived by technician-measured systolic time intervals, the approach employed in the present and all other previous studies. In addition, the same study[7] included 82 patients with complicating disorders in addition to coronary artery disease, particularly mitral regurgitation, which has been shown to increase PEP/LVET above the level caused by abnormal left ventricular performance.[17]

The failure to include data on normal subjects by which one could compare methodologic approaches in three of the studies[7–9] makes it impossible to assess the magnitude of the differences in measurements that these methodologic variations might have imposed. The one study that did use normal control subjects[6] suggests that these alterations in equipment and methods are indeed important. The upper limit of normal for PEP/LVET in that study was 0.48, a level that is well into the abnormal range when standard methods are employed. In two independent reports by Lewis and co-workers[4,17] in which methods identical to that used in this study were employed, correlations between PEP/LVET and left ventricular ejection fraction were 0.85 and 0.76, respectively, in patients with chronic coronary artery disease. The r values in these reports do not differ significantly from that in the present investigation. Thus there was close agreement in all correlation studies employing methods of determining the systolic time intervals identical to that reported in the present study. Major reductions in the r values were observed in the studies in which methodologic differences were introduced into the systolic time interval determinations. Thus, methodologic variations offer the most plausible explanation for the differences in closeness of fit between ejection fraction and PEP/LVET data in these previously reported studies.[6–9]

PEP/LVET versus ejection fraction to detect left ventricular dysfunction: The group analysis of the data in the current study permitted comparison of the capacity of PEP/LVET and left ventricular ejection fraction to separate patients with normal performance from those with left ventricular dysfunction. Among the patients with coronary artery disease with and without previous myocardial infarction, the PEP/LVET proved equivalent to the ejection fraction in identifying the patients with abnormal left ventricular performance. The specificity and sensitivity calculations permitted a test of the accuracy of PEP/LVET in detecting the presence of a normal and abnormal ejection fraction among the pooled population of patients with and without coronary artery disease. This form of data analysis was selected in order to approach the question of the clinical applicability of PEP/LVET measurements in identifying patients with abnormal and normal ventricular performance by angiographic ejection fraction among a mixed population of patients. Clearly, the high degree of specificity and sensitivity denotes that an abnormal PEP/LVET predicts the presence of an abnormal ejection fraction, and its significance in clinical interpretation would be similar to that of the latter. The calculation of the percent agreement between the two measures in detecting the presence of left ventricular dysfunction in the clinical subgroups of patients validates the use of PEP/LVET in segregating subpopulations of patients with abnormal left ventricular performance. The presence of an abnormal ejection fraction in patients with more extensive coronary arterial obstruction and with high end-diastolic pressure

was detected with a high degree of accuracy by the measurement of PEP/LVET. The use of the nonparametric and logistic regression analysis permitted precise comparison and subsequent independent analysis of both PEP/LVET and ejection fraction in this nonnormally distributed patient population.

Clinical implications: The studies summarized herein reflect the virtual equivalence of the PEP/LVET and the angiographically determined ejection fraction in defining the presence of normal or abnormal left ventricular performance in the resting supine patient with coronary artery disease. On the basis of the group data analysis, the high level of correlation, the high degree of specificity and sensitivity of PEP/LVET in defining normal and abnormal data points for left ventricular ejection fraction, the agreement in clinical subsets of patients, and logistic regression analysis, it can be concluded that PEP/LVET affords an accurate expression of the global performance of the left ventricle in coronary artery disease. The agreement between this noninvasive estimate of left ventricular performance and the ejection fraction measurement in individual patients supports the application of systolic time intervals as a readily obtainable and reliable clinical measure of left ventricular performance when methodologic standards are maintained. The safety, reliability and easy accessibility of the systolic time intervals suggests their application in future clinical studies on factors influencing left ventricular performance in coronary artery disease.

A comparison of left ventricular function data derived from a low cost, portable electrocardiographic gated scintillation probe (nuclear stethoscope) with conventional scintiangiographic data was performed in 68 patients. Ejection fraction correlation ($r = 0.86$, $p < 0.005$) was better in patients with uniform wall motion than in those with regional asynergy ($r = 0.68$ $p < 0.01$). Probe variables reflecting systolic emptying rates, diastolic filling rates and timing intervals, and relative volumes analyzed in combination provided 100 percent sensitivity, specificity, and predictive value in detecting abnormal left ventricular performance. The results suggest that radionuclide angiography with an electrocardiographic gated scintillation probe is a sensitive, rapid and relatively inexpensive portable method of screening for cardiac dysfunction with a yield similar to that from the more costly gamma camera derived scintiangiogram.

Nonimaging electrocardiographic gated radiation detection systems have been utilized for more than 30 years to provide clinically useful noninvasive measurements of cardiac function.[1] Radiocardiograms from low temporal resolution scintigraphic probe systems (0.5 second per data point) were first used to derive cardiac output, pulmonary transit times and intracardiac shunts.[2–9] With the development of higher temporal sampling probe systems, ejection fraction could be derived from these first transit radiocardiograms.[10] The advent of scintigraphic gamma camera imaging systems, electrocardiographic gating, and sophisticated minicomputers dedicated to the production of dynamic cardiac blood pool imaging has made possible scintigraphic qualitative assessment of cardiac wall motion. Analysis of sequential count data in a spatially defined area of interest from numerous aggregated cardiac cycles can then be performed. A representative single cardiac cycle time-activity (volume) curve results, from which quantification of ejection fraction, volumes and other function variables can be derived.[11,12]

Although these elaborate dynamic cardiac imaging systems provide clinically useful data, their cost is great in terms of equipment and specially trained manpower required. Spatial imaging requires human and computer processing of data that often delays the immediate availability of scintiangiographic results. Substitution of temporal for spatial resolution (time-activity curve quantification rather than dynamic heart imaging) utilizing electrocardiographic gated scintillation probe devices allows approximately a 10-fold reduction in size and expense when compared with conventional imaging gamma cameras. An electrocardiographic gated scintillation probe device incoporating new microprocessor technology enables acquisition, calculations and display of results virtually instantaneously after proper placement of the probe with a separate imaging system.[13] Another probe system, the Nuclear Stethoscope (Bios, Valhalla, New York), incorporates such microprocessor technology with a unique positioning strategy to locate the left

ventricular cavity in an otherwise position-blind electrocardiographic gated scintillation probe device.[14–16] This report compares the findings of this portable system with those from the more elaborate and expensive dynamic heart imaging system in the detection of left ventricular dysfunction.

Methods

The nuclear stethoscope: A unique gamma scintillation probe, the nuclear stethoscope, consisting of an electrocardiographic gated scintillation probe and dedicated microprocessor, combines a 2 inch (5 cm) thallium drifted sodium iodide detector with a converging collimator designed to give a 2.75 inch field of view at the focal plane of the heart 1.5 inches from the face of the collimator when placed on the chest wall over the precordium. It contains an Intel 8085 microprocessor programmed to measure, calculate and display data in real time over a 256 by 256 element matrix utilizing 6K programmable and 4K random access memory. Monitoring modes utilize an electrocardiographic gating system designed to sense R waves and reject premature beats. Noise artifact is automatically filtered out. The beat to beat position monitor mode allows analysis of individual beats and a positioning algorithm strategy. In this mode, the microprocessor provides an independent means of identifying the optimal sites for both left ventricular and background sampling. The electrocardiographic dependent positioning algorithms are designed to detect regions of interest demonstrating maximal stroke volume as well as to differentiate between right and left ventricular end-diastolic volumes. The background site is also detected by a positioning algorithm that is maximally satisfied when stroke volume is minimal and out of synchronization with the electrocardiographic signal. Background is then automatically subtracted before analysis of data to compensate for "false" information contributed by contiguous isotope-containing structures.

Study patients: Sixty-eight patients were referred for diagnostic imaging because of known or suspected heart disease. All patients had Anger camera and nuclear stethoscope studies in random order, performed independently by different technicians in separate rooms following administration of 15 to 20 mCi technetium-99m–labeled human serum albumin. Routine blood pool imaging, using an Ohio Nuclear Camera-V.I.P. 550 system in anterior and 30° left anterior oblique views, was obtained as a basis for comparison with the probe data. Left ventricular ejection fraction in the 30° left anterior oblique view was quantitated and wall motion in both views was qualitatively assessed with use of a previously validated methodology.[17] Abnormal cardiac function was defined as a left ventricular ejection fraction of less than 0.50 or a regional wall abnormality.

Analysis of data and calculations: All nuclear stethoscope data were analyzed by an experienced operator. Equilibrium mode monitoring of the patient's left ventricle was obtained in both beat to beat and gated ventricular function modes. The latter mode produced high fidelity left ventricular time-activity curves with 20,000 to 30,000 counts in the end-diastolic frame (aggregation of count data from 30 to 45 beats after a standard study dose of 15 mCi of technetium-labeled blood pool agent). The higher temporal resolution gated ventricular function mode (10 ms per data point) was selected over the lower temporal resolution beat to beat mode (50 ms per data point) for statistical analysis.

The following left ventricular indexes were obtained from the net left ventricular time-activity curves (Fig. 1), updated, and displayed by the nuclear stethoscope microprocessor in real time:

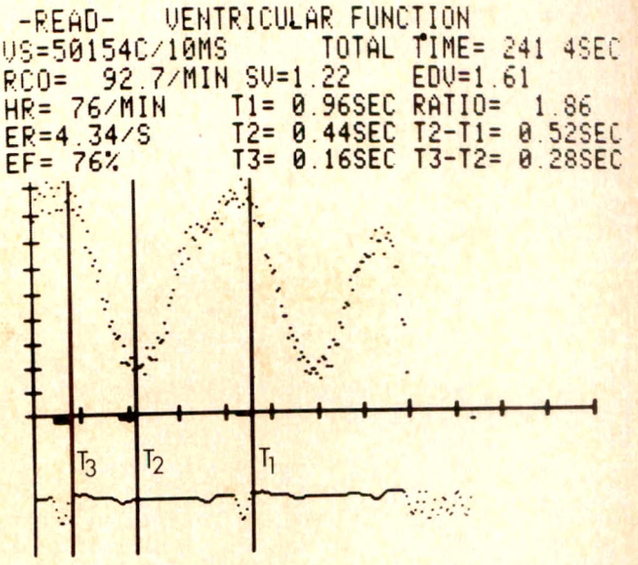

FIGURE 1. High temporal resolution left ventricular time-activity curve obtained by monitoring a blood pool radioisotope with a portable electrocardiographic gated scintillation probe device (nuclear stethoscope). Cardiac timing intervals, ejection fraction (EF), heart rate (HR), ejection rate (ER) and relative volumetric variables of stroke volume (SV) and end-diastolic volume (EDV) can be derived by microprocessor in real time from this typical display, providing immediate clinical data feedback. Cursors (T_3-T_2) have been placed by the operator to bracket the systolic ejection time and combined rapid and slow diastolic filling phases (T_2-T_1). Each data point represents a sampling time of 10 ms.

$$\text{Ejection fraction} = \frac{\text{End-diastolic counts} - \text{End-systolic counts}}{\text{End-diastolic counts} - \text{Background counts}} \quad (1)$$

$$\text{Relative stroke volume} = \frac{\text{End-diastolic counts} - \text{End-systolic counts}}{0.5\,\{(\text{End-diastolic counts} + \text{End-systolic counts}) - (\text{Background counts})\}}. \quad (2)$$

$$\text{Relative end-diastolic volume} = \frac{\text{End-diastolic counts}}{(0.5)\{(\text{End-diastolic counts} + \text{End-systolic counts}) - \text{Background counts}\}} \quad (3)$$

$$\text{Relative cardiac output} = \text{Heart rate} \times \text{Relative stroke value} \quad (4)$$

$$\text{Ejection rate} = \frac{\text{End-diastolic counts} - \text{End-systolic counts}}{(0.5)\{(\text{End-diastolic counts} + \text{End-systolic counts}) - \text{Background counts}\}} \times \frac{1}{\text{Left ventricular ejection time}}. \quad (5)$$

$$\text{Fast-filling rate} = \frac{\text{End-diastolic counts} - \text{End systolic counts}}{(0.5)\{(\text{End-diastolic counts} + \text{End-systolic counts}) - \text{Background counts}\}} \times \frac{1}{\text{Left ventricular fast filling time}}. \quad (6)$$

Relative volumetric variables (stroke volume and end-diastolic volume) could potentially be converted to absolute variables within this system by comparison with the absolute cardiac output derived in a separate nuclear stethoscope operating mode, the first transit mode. In first transit mode, monitoring a bolus injection as it passes through the heart provides a traditional radiocardiogram suitable for microprocessor derivation of absolute cardiac output by standard Hamilton-Stewart analysis. Comparison of the initial first transit cardiac output with subsequent monitoring mode relative cardiac output provides a calibration factor. This factor allows conversion of all subsequent gated monitoring mode relative volumetric variables to absolute terms. Relative variables are in units of counts per unit time, and absolute variables are in conventional units of milliliters per unit time. Relative volumetric variables were chosen for analysis to eliminate the necessity of an adequate bolus injection required in the first transit mode and subsequent conversion process.

The following temporal subdivisions of the cardiac cycle time-activity curve were displayed after operator placement of cursors (method of Qureshi et al.)[18]*:*

1. *Preejection period* = period of electromechanical delay and isovolumic contraction. This represents the initial plateau phase of the curve.
2. *Left ventricular ejection time* = period of ventricular emptying with onset at the first change in slope from the preejection period plateau and termination when the slope goes through zero at the nadir of the curve.
3. *Left ventricular fast filling time* = period of rapid ventricular filling after aortic valve closure. This period begins with protodiastolic cessation of ventricular ejection and concludes with the onset of left ventricular diastasis represented by a blunting of the upward slope of the curve.
4. *Left ventricular diastasis time including atrial systole* = slow phase of ventricular filling before the next systole, taken from the point where the rapid rise of ventricular filling suddenly slows to the end of the cardiac cycle.

In addition to this analysis, a rate-related analysis of each variable by dividing each subdivision of the time-activity curve by the total cycle time was performed and displayed in real time throughout the acquisition and recorded at the completion of the study. The average study required 10 to 20 minutes for completion. The optimal left ventricular site was generally 1 to 5 cm medial to the point of maximal impulse in a 30° to 40° left anterior oblique orientation with a 10° caudal tilt. The optimal background site was usually midway between the left ventricular apex and the spleen in the same left anterior oblique orientation.

Reproducibility: Results could be reproduced with less than 5 percent variation by using the positioning algorithm. All patients had duplicate studies with less than 5 percent difference in ejection fraction on consecutive probe placement and acquisition as well as serial repeated observations at the identical sampling site considered a valid collection. Acquisition was noted to be position-dependent: Displacement of the probe-chest orientation by 2 to 3 cm significantly altered results. A 30 case load experience produced uniform reproducibility, probably as a consequence of learned hand-eye coordination of algorithm-guided probe placement. The data in this study were acquired by a single operator whose experience included more than 200 cases.

Statistical analysis: Inference of significance in the various nuclear stethoscope variables was derived from a Student distribution analysis with two tails and represents at least a probability (p) value of <0.05 except as otherwise stated. Inference of significance for Y intercept values from regression analysis of ejection fractions is based on limits on predicted individual values assuming homoscedasticity as well as by the standard error of the estimate analysis on the Y intercept.

Results

Standard gamma camera imaging identified abnormalities in 50 patients (ejection fraction less than 0.50 or a regional wall motion abnormality) and normal findings (ejection fraction greater than 0.50 and normal wall motion) in 18. A decreased ejection fraction (less than 0.50) was found in 47 of the 50 patients in the abnormal group, and wall motion abnormalities were detected in 26 (52 percent). Of the 47 patients with a decreased ejection fraction, 23 (49 percent) had regional wall motion abnormalities. Three of the 50 patients (6 percent) had abnormal wall motion and a normal ejection fraction. There were no statistically significant differences in age or sex distribution in the normal and abnormal groups.

Effect of wall motion abnormalities on left ventricular ejection fraction: To evaluate the effect of localized wall motion abnormalities on nuclear stethoscope-determined left ventricular values, patients were grouped according to presence or absence of asynergy on standard gamma camera imaging. Group 1 consisted of 42 patients with uniform wall motion, either normal (Group Ia, n = 18) or diffusely hypokinetic (Group Ib, n = 24). Group II consisted of all patients with asynergy (n = 26). There was a good relation between ejection analysis from the gamma camera and those from the nuclear stethoscope in Group I ($r = 0.86$, $p < 0.005$) (Fig. 2A). Nuclear stethoscope and gamma camera comparison of left ventricular ejection fraction in Group II yielded a lower correlation ($r = 0.68$, $p < 0.01$) (Fig. 2B). Linear regression analysis revealed that the nuclear stethoscope-derived ejection fraction consistently overestimated gamma camera ejection fraction. This overestimation was significantly greater in Group II (patients with asynergy).

Background determination was analyzed in all patients. Mean background determination was 75 percent of maximal end-diastolic counts in Group Ia, 73 percent in Group Ib and 83 percent in Group II.

Analysis of left ventricular variables (sensitivity, specificity, predictive value): Mean, standard deviation and standard error of the mean were calculated for each nuclear stethoscope-derived variable of left ventricular function in both normal and abnormal groups. Standard error of the mean analysis was in turn used to calculate standard error of the difference for each value (Table I). This analysis revealed widest separation in the distribution of results in the normal and abnormal populations for the relative cardiac output, ejection rate, fast filling rate, the ejection fraction and the ejection fraction divided by the fast filling time. Confidence levels of 66.8 percent (mean less 1 standard deviation) and 95 percent (mean less 2 standard deviations) were determined for these values derived from Group Ia (patients with normal, uniform wall motion) and compared with results in the total group of patients with abnormalities (Group Ib, uniform diffuse hypo-

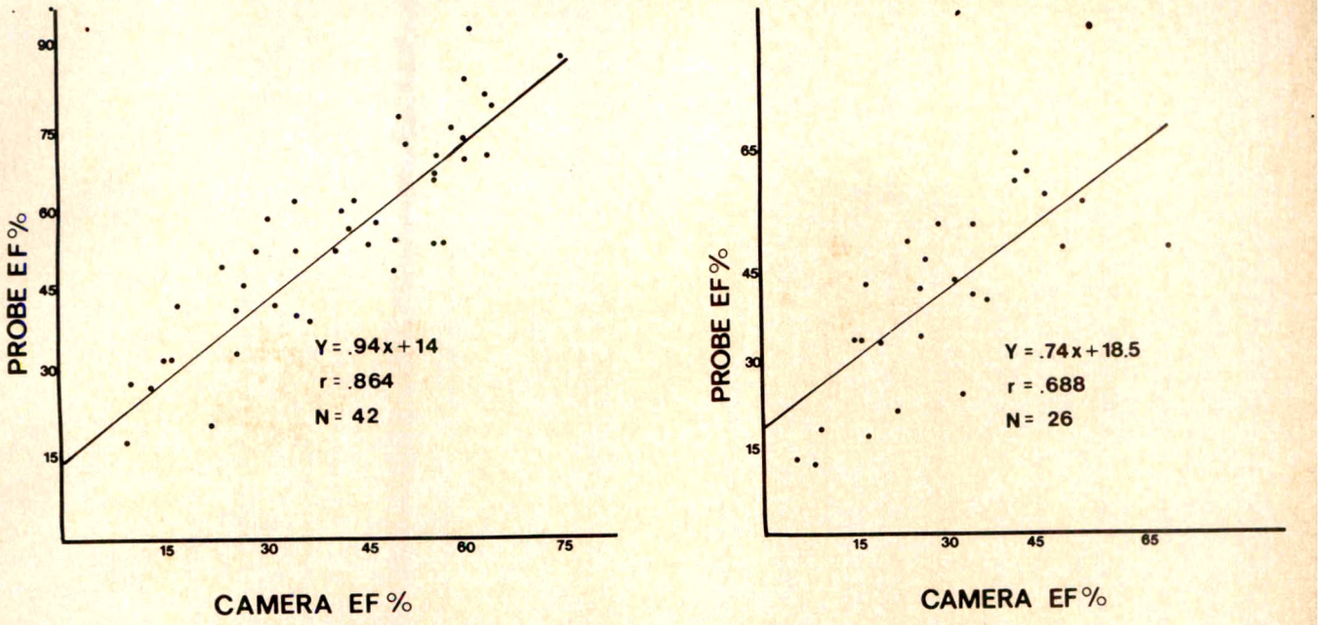

FIGURE 2. Linear regression analyses of ejection fraction (EF) measurements derived by the conventional Anger camera-computer system with those from the nuclear stethoscope probe system. **Left,** shows the correlation in the 42 patients determined by camera-computer–derived scintiangiogram to have uniform wall motion (normal [Group Ia] or diffusely hypokinetic [Group Ib]). **Right,** the poorer correlation in the 26 patients found by camera study to have regional left ventricular asynergy (Group II).

kinesia, and Group II, asynergy) (Fig. 3). Ninety-five percent confidence levels for the nuclear stethoscope-derived ejection fraction in the 50 abnormal patients predicted 44 (88 percent) patients with abnormality. When 66.8 percent confidence levels for the nuclear stethoscope variables in the normal group were defined as a cutoff value in separating normal from abnormal function, more sensitive variables for the detection of abnormal function emerged (ejection fraction 100 percent sensitivity, relative stroke volume 100 percent, relative end-diastolic volume 100 percent, relative cardiac output 98 percent, ejection rate 96 percent, fast filling rate 94 percent, ejection fraction divided by fast filling time 92 percent). Specificity was reduced in certain variables (relative cardiac output 100 percent, ejection rate 89 percent, fast filling rate 89 percent, ejection fraction divided by fast filling time 88 percent, relative stroke volume 83 percent, relative end-diastolic volume 83 percent, ejection fraction 83 percent). Predictive value analysis identified relative cardiac output (100 percent), ejection rate (96 percent), fast filling rate (96 percent), and ejection fraction divided by fast filling time (96 percent) as better individual measures of abnormal performance than ejection fraction (94 percent) (Table II). In all patients studied, any two of three of these nuclear stethoscope variables—relative cardiac output, ejection rate, fast filling rate or ejection fraction divided by fast filling time—falling above or below the 66.8 percent confidence level correctly identified all patients determined with the gamma camera to be in the normal or abnormal group (100 percent sensitivity, specificity and predictive value).

Discussion

Ejection fraction to monitor left ventricular function: Assessment of left ventricular function by ejection fraction and wall motion analysis with scintillation camera and dedicated computer correlates closely with cardiac catheterization results and has been widely accepted as a noninvasive method for evaluation of cardiovascular physiology.[17–27] The results of this study suggest that the nuclear stethoscope can effectively be used to detect left ventricular dysfunction by monitoring ejection fraction. Comparison of gamma camera and nuclear stethoscope ejection fraction measurements revealed excellent correlation in patients with uniform wall motion and acceptable correlation in patients with nonuniform wall motion. A small group of four patients with a depressed gamma camera ejection fraction had a normal ejection fraction by nuclear stethoscope. Another subset of four patients had a normal ejection fraction by both gamma camera and nuclear stethoscope and abnormal regional wall motion on scintiangiography. In both subsets other nuclear stethoscope variables reflecting left ventricular systolic emptying rates, diastolic filling rates, diastolic timing intervals and relative cardiac output and volumes were able to predict abnormal ventricular performance as determined by gamma camera criteria despite a normal probe ejection fraction. This is not unexpected because it is reasonable that some patients with abnormal function will have significant alterations of systolic and diastolic flow rates and timing intervals in the presence of a normal ejection fraction.

* An abnormal value was defined as a value below the mean normal value less standard deviation (66.8 percent confidence level). † 95 percent confidence level. ‡ Combined scoring system: the presence of any two of the three variables above or below the 66.8 percent confidence level represents normal or abnormal function, respectively.

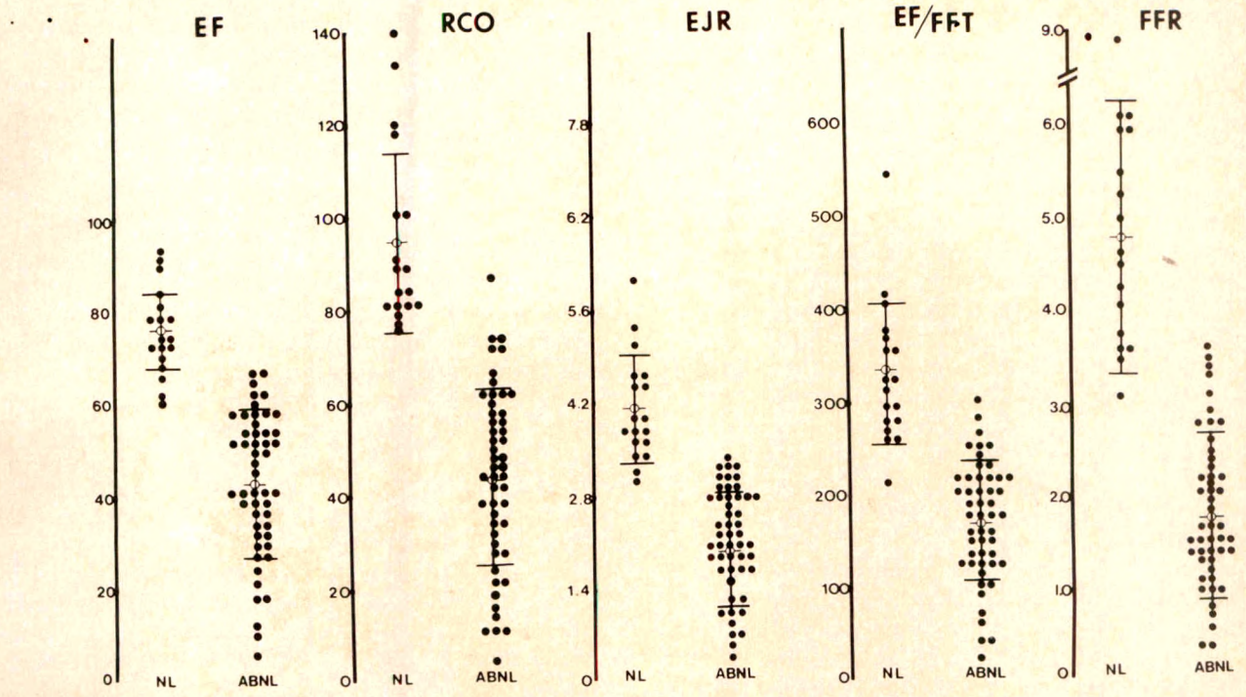

FIGURE 3. Distribution of selected left ventricular function variables derived from the nuclear stethoscope time-activity curves. Patients with a normal (NL) or abnormal (ABNL) left ventricle were so defined by conventional Anger camera scintiangiographic criteria. EF = ejection fraction; FFR = fast filling rate; EF/FFT = ejection fraction divided by the fast filling time; EJR = ejection rate; RCO = relative cardiac output. **Open circles** represent the mean and **bars** represent ±1 standard deviation.

Left ventricular ejection rate versus ejection fraction: Radioisotopic quantification of left ventricular ejection rate acquired by first pass imaging methods with a multicrystal camera-computer system[28] and by gamma camera gated equilibrium techniques[29] has proved as sensitive as radioisotopic ejection fraction analysis in detecting abnormal left ventricular performance. A significant reduction in fast filling rate was uniformly found in patients with angiographically validated coronary artery disease in the absence of hypertrophy or valve disease by Young et al.[30] using first pass multicrystal camera techniques. Significant rate-related prolongation of the fast filling time was shown by Qureshi et al.[18] in patients with hypertensive, ischemic or idiopathic cardiomyopathy with the gated equilibrium imaging technique. In our study, the crude systolic and diastolic timing intervals were as useful for detecting ventricular dysfunction as were the more complex rate-corrected timing interval analysis. However, no single probe-derived timing interval proved a better predictor of dysfunction than ejection fraction. There was a tendency of the fast filling time to prolong in the abnormal group relative to the ejection fraction-matched normal population. Nonetheless, the timing intervals may provide useful information in particular clinical settings or in characterizing a specific cardiomyopathy.

Relative cardiac versus output ejection fraction: The best single predictor of dysfunction, the relative cardiac output, is most problematic. This represents the double product of heart rate and relative stroke volume. A small group of patients with regional dyskinesia by Anger camera studies had depressed nuclear stethoscope-derived relative cardiac output and relative stroke volume, despite an ejection fraction that fell within the established normal range. Diminution in the relative cardiac output and relative stroke volume could represent the nuclear stethoscope impression of a "reduced" left ventricular volume by virtue of a noncontracting segment of the chamber identified and subtracted away mistakenly as background. This is further suggested by the significant overestimation by the nuclear stethoscope of ejection fraction in patients with regional wall motion abnormalities (Group II) compared with the ejection fraction in the combined group of patients with normal and global hypokinesia (Groups Ia and Ib).

Methodologic problems: The ejection fraction by nuclear techniques is derived by the standard formula:

Ejection fraction percent = End-diastolic counts − End-systolic counts × 100/End-diastolic counts − background counts

Systematic overestimation of background would produce an overestimation of global ejection fraction. Analysis of mean background determinations revealed such a significant increase in background in Group II when compared with values in Group Ia and Group Ib. This anomaly of the nuclear stethoscope data is also

presumably in part created by the positioning strategy, which tends to locate the probe field of view over the best contracting segment of the left ventricle, while excluding counts from poorly contracting segments and instead incorrectly adding these valid left ventricular counts to the background field of view. The relative cardiac output would thus prevent the overestimation of left ventricular function obtained in patients with regional asynergy with use of ejection fraction analysis alone because the background subtraction is weighted less in the relative cardiac output than in the ejection fraction analysis. This method of analysis produces a greater overestimation of ejection fraction than of relative cardiac output proportional to the extent of dyskinesia of the left ventricle. Comparison of ejection fraction with relative cardiac output ratios could potentially predict regional wall motion abnormalities (ischemic cardiomyopathy) with this nonimaging detector system.

Sensitivity, specificity and predictive value of method: The relative cardiac output, ejection rate, fast filling rate, and ejection fraction divided by the fast filling rate are the most accurate single nuclear stethoscope predictors of cardiac dysfunction. The sensitivity and specificity for the detection of dysfunction are expanded by considering these variables together. All patients with abnormal results on gamma camera analysis could be accurately selected out when two of any three of these variables were abnormally depressed (defined as 1 standard deviation less than the mean value derived from the normal population). All patients with normal gamma camera studies could be identified by normal values for two of any three of these variables.

Implications: These results suggest that radionuclide angiography with an electrocardiogram gated scintillation probe is a sensitive, rapid and potentially cost-effective portable method for screening for left ventricular dysfunction. The diagnostic yield from the nuclear stethoscope compares favorably with that from the more elaborate and costly gamma camera-computer system. Because stress testing in conjunction with imaging, contrast or radionuclide, increases the sensitivity for the detection of coronary artery disease, probe-monitored stress tests may provide an even more sensitive technique than the resting procedure described in this study. High temporal resolution time-activity curves recorded by this device provide numerous variables of left ventricular function that appear to be more sensitive and specific than ejection fraction analysis alone in a detection of abnormal ventricular performance. A large scale clinical trial is needed to determine the predictive value of probe-derived variables for defining the specific nature of cardiac dysfunction as well as the utility of probe-monitored stress tests.

The ability of radionuclide angiocardiography to quantitatively assess regional left ventricular function was studied in 33 patients undergoing biplane left ventricular cineangiography (45° right anterior oblique projection, and 60° left anterior oblique projection with 25° caudocranial angulation), and first pass (30° right anterior oblique projection) and multiple gated equilibrium (35° to 45° left anterior oblique projection with 20° to 25° caudocranial angulation) left ventricular scintigraphy within 48 hours. End-diastolic and end-systolic silhouettes of contrast angiograms were superimposed, and five segments were defined in each plane by radial lines originating from the end-diastolic center of mass. Segmental angiographic ejection fraction (end-diastolic area − end-systolic area/end-diastolic area) was calculated for each segment by computerized planimetry. Similar segments were defined in the end-diastolic and end-systolic regions of interest of the first pass and gated left ventricular scintigrams, and the segmental scintigraphic ejection fraction (background-corrected end-diastolic counts − background-corrected end-systolic counts/background-corrected end-diastolic counts) was obtained for each.

A good correlation was observed between segmental angiographic and scintigraphic ejection fraction in the segments corresponding to the anterobasal ($r = 0.74$), anterolateral ($r = 0.70$), apical ($r = 0.77$), diaphragmatic ($r = 0.71$), distal septal ($r = 0.66$), posterolateral ($r = 0.71$) and inferolateral ($r = 0.60$) left ventricular regions. The poor correlation in the posterobasal ($r = 0.39$), basal septal ($r = -0.02$) and superolateral ($r = 0.05$) segments was probably related to difficulty in defining the aortic valve, overlap of the left atrium and the left ventricle, and inability to visualize the high septum with these scintigraphic techniques. The reproducibility of scintigraphic segmental ejection fraction was studied in 13 patients in whom a second gated scintigram was performed 2 hours after the initial one. Excellent agreement ($r = 0.93$) was observed for scintigraphic segmental ejection fraction in the distal septal, posterolateral and inferolateral segments. Segmental scintigraphic ejection fraction enables accurate quantitative evaluation of the function of the anterobasal, anterolateral, apical, diaphragmatic, distal septal, posterolateral and inferolateral left ventricular regions with high reproducibility.

Accurate analysis of regional left ventricular performance is of particular interest in patients with coronary artery disease, in whom neighboring areas of normal and abnormal left ventricular function are frequently present at rest or develop during exercise. Traditionally, contrast angiography has been employed to assess left ventricular function,[1–3] but more recently radionuclide angiocardiography has become available and has proved valuable in the evaluation of left ventricular function in these patients.[4–7] However, it has been shown that subjective analysis of left ventricular angiograms and scintigrams is characterized by a significant error rate and interobserver variability,[8–11] and objective analysis is essential for adequate definition and quantification of regional left ventricular function.

Several methods have been employed for objective evaluation of regional function with contrast left ventricular angiograms,[12–16] and some of these have been applied to the analysis of radionuclide angiocardiograms.[5,17–19] These angiographic methods, usually based on segmental changes in radii, hemiaxes or area, require precise identification of left ventricular margins, and are limited by the spatial resolution and edge definition of radionuclide studies. In addition, these methods ignore the three dimensional perspective provided by radioactive emission and thus limit the information to a single plane.

The purpose of this study was to develop a method that would enable accurate quantitative assessment of regional left ventricular function employing first pass and multiple gated radionuclide angiocardiography.

Methods

Patients

The study group consisted of 33 patients, 27 men and 6 women, undergoing diagnostic cardiac catheterization for suspected ischemic heart disease. The mean age of the patients was 53 years (range 37 to 73). In the postabsorptive state, approximately 60 minutes after premedication with atropine, 0.6 mg intramuscularly, and diphenhydramine (Benadryl®), 50 mg orally, all patients underwent right and left cardiac catheterization. Initial hemodynamic determinations were followed by biplane left ventricular cineangiography and selective coronary arteriography. Twenty-nine patients were found to have coronary artery disease (70 percent or greater reduction in luminal diameter of at least one major coronary artery), and 4 had no evidence of cardiac disease. Within 48 hours of contrast angiography, and during stable hemodynamic conditions, all patients underwent first pass and multiple gated equilibrium left ventricular scintigraphy. Patients receiving medications were maintained on the same dosage and no changes were made in the interval between angiographic and scintigraphic studies.

Angiographic Studies

Biplane left ventricular cineangiograms were performed in a 45° right anterior oblique projection and 60° left anterior oblique projection with 25° caudocranial ("axial") angulation. These projections, performed routinely at our institution, improve the evaluation of left ventricular wall motion without compromising left ventricular volume quantitation in comparison with data obtained from conventional 30° right anterior oblique and 60° left anterior oblique biplane cineangiography.[20] Filming was performed at 30 frames/s during power injection of 60 ml of sodium and meglumine diatrizoates (Renografin®-76) through an 8 French Cook pigtail catheter over a period of 3 seconds.

Data processing: Left ventricular volumes and ejection fraction were determined from biplane end-diastolic and end-systolic frames using area-length method.[21] Frames were selected by visual inspection, and films exposed during premature contractions or the following cycle were excluded from analysis. Regional left ventricular function was assessed angiographically by a method previously reported from our institution[22] that has been shown to define and quantitate regional left ventricular contraction accurately. Figures 1 and 2 illustrate this method in a patient with triple vessel coronary disease and severe left ventricular dysfunction. Consecutive end-diastolic and end-systolic frames were traced by trained technicians and superimposed using two external X-ray beam markers as a reference system. The ventricular silhouettes were then digitized with the stylus of a spark-gap x-y digitizing pen (Graf/Pen Science Accessories Corp., Southport, Connecticut) interfaced to an IBM 1800 computer system.[23]

In the right anterior oblique projection (*Fig. 1*), the center of mass of the end-diastolic silhouette (obtained as the average

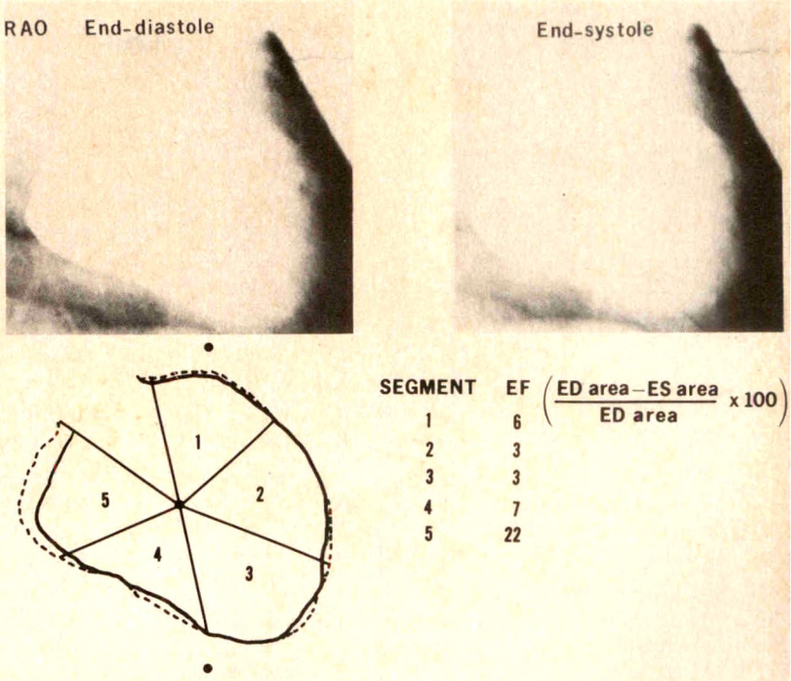

FIGURE 1. End-diastolic (ED) (**upper left**) and end-systolic (ES) (**upper right**) frames of a right anterior oblique (RAO) left ventriculogram in a patient with severe coronary artery disease and left ventricular dysfunction. In the **lower panel** (**left**), the end-diastolic (**dashed line**) and end-systolic (**solid line**) silhouettes have been superimposed using two external X-ray beam markers (**solid dots**). Five segments have been defined as described in the text, and segmental angiographic ejection fraction (EF) calculated for each (**right**).

x and y position of all discrete points within the silhouette[24]) was used as the vertex of the angle between the left margin of the aortic valve and the apex. This angle was divided into fifths. Segment 1 (anterobasal) comprised the first two fifths of the angle and segment 2 (anterolateral) the next two fifths. The angle between the right margin of the aortic valve and the apex was obtained similarly and also divided into fifths. Segment 5 (posterobasal) was the first two fifths of this angle, and segment 4 (diaphragmatic) was the next two fifths. Segment 3 (apical) was the remaining area from the left and right sides. In this manner, five segments were defined in the right anterior oblique projection.

In the axial left anterior oblique projection (*Fig. 2*), the center of mass of the end-diastolic left ventricular silhouette was also used to define the angle between the right margin of the aortic valve and apex. This angle was bisected, giving segments 6 (basal septal) and 7 (distal septal). The angle between the left margin of the aortic valve and apex was divided into three equal angles, segments 8 (posterolateral), 9 (inferolateral) and 10 (superolateral).

Segmental angiographic ejection fraction was calculated for each segment by computerized planimetry as follows: Segmental angiographic ejection fraction = [(segmental end-diastolic area − segmental end-systolic area)/segmental end-diastolic area)] ×100.

Radionuclide Studies

Within 48 hours of contrast angiography, and during stable and unchanged hemodynamic conditions, first pass and gated blood pool left ventricular angiocardiograms were obtained in all patients. The gamma camera was positioned in a 30° right anterior oblique projection for the first pass studies and in a 35° to 45° left anterior oblique projection with 20° to 25° of caudocranial angulation for the gated studies. Thus the right anterior oblique angiographic projection was similar to the first pass scintigraphic projection, and the axial left anterior oblique angiographic projection was similar to the gated scintigraphic projection.

Radionuclide studies were obtained using a mobile single crystal scintillation camera (Ohio Nuclear Series 120) equipped with digital magnetic tape and an all purpose parallel hole collimator. Red blood cells were labeled in vivo[25] by injecting 3 mg of stannous pyrophosphate (Pyrolite,® New England Nuclear) 30 minutes before the injection of 18 to 20 mCi of technetium-99m pertechnetate as a bolus dose into an antecubital vein, or into the right atrium in patients with a double lumen Swan-Ganz catheter positioned in the pulmonary artery. The first passage of activity was recorded on magnetic tape in list mode at a maximal rate of 30,000 counts/s. For 20 mCi and the particular collimator used, count rate saturation occurred only at the initial passage of the bolus injection into the right heart chambers.

Patients remained at bed rest after the first pass study, and after equilibration of the radionuclide in the vascular space (10 to 15 minutes), the gated blood pool study was performed. The data were stored on magnetic tape with the electrocardiographic signal stored as 1 pixel in a 256 by 256 matrix in a digitized frequency modulated format. In this use, the magnetic tape had a maximum count rate of 15,000 counts/s, but the practical maximum was approximately 11,000 counts/s to ensure that the electrocardiographic signal would not be subject to pulse pile-up effects. The tape unit had 6 minutes of recording time for a total of 3 to 3.5 million events for the complete study.

Data processing: Processing of the data was accomplished with an Informatek computer (Simis 3). For first pass studies, data were read and stored on the computer disk in list mode. Regions of interest were drawn over the superior vena cava, the right ventricle and the left ventricle. Time-activity curves for 1 second intervals were formed from each region of interest, and were used for quality control of the bolus of activity. The left ventricular time-activity curve was used to define the levophase for high frequency framing. Three to six beats were selected, and a composite cardiac cycle was formed consisting of 16 sequential frames (30 to 60 ms/frame). For processing of the gated blood pool studies, data were replayed through

FIGURE 2. End-diastolic (ED) (**upper left**) and end-systolic (ES) (**upper right**) frames of an axial left anterior oblique (LAO) left ventriculogram in the same patient as in Figure 1. In the **lower panel** (**left**), end-diastolic (**dashed line**) and end-systolic (**solid line**) silhouettes have been superimposed using external X-ray beam markers (**solid dots**). Five segments have been defined as described in the text, and segmental angiographic ejection fraction (EF) calculated for each (**right**).

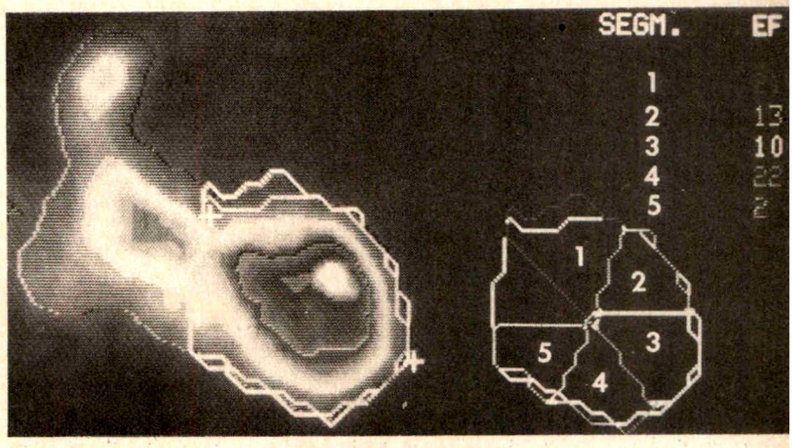

FIGURE 3. Superimposed end-diastolic left ventricular regions of interest of a right anterior oblique first pass scintigram in the same patient as in Figures 1 and 2. On the **right**, the regions of interest are divided into five segments (SEGM.) as described in the text, and the segmental scintigraphic ejection fraction (EF) is listed for each.

a magnetic tape unit interfaced to the computer. The electrocardiographic signal was reconstructed and used by the computer to gate the position data into 16 time intervals between R waves.

The first pass and gated equilibrium data were presented in a similar format, and the same program was used for processing each. The processing technique followed that of Pavel and co-workers[26,27] with modifications. After spatial smoothing, end-diastolic and end-systolic left ventricular regions of interest were formed by the isocount contours that best encompassed those images, and a valve plane was manually drawn to close each region of interest. As an aid for contour selection, edge-enhanced images were used in conjunction with the end-diastolic and end-systolic images. A computer-initiated background region of interest was formed around the apex and lateral wall of the left ventricle on the end-systolic image. Time-activity curves for the end-diastolic and end-systolic regions of interest were formed.

Left ventricular ejection fraction was calculated as follows:

$$\text{Ejection fraction} = [(ED_d - B_d) - (ES_s - B_s)/(ED_d - B_d)] \times 100,$$

where ED_d = end-diastolic counts from the end-diastolic time-activity curve; B_d = background normalized to the number of pixels in the end-diastolic region of interest; ES_s = end-systolic counts from the end-systolic time-activity curve; and B_s = background normalized to the number of pixels in the end-systolic region of interest.

The method employed for quantitative analysis of regional left ventricular function from first pass and multiple gated blood pool scintigrams is illustrated in Figures 3 and 4, for the same patient whose contrast left ventriculograms are shown in Figures 1 and 2. The superimposed end-diastolic and end-systolic regions of interest in the first pass (Fig. 3) and multiple gated blood pool (Fig. 4) scintigrams were divided in five segments by radial lines originating from the center of mass of the end-diastolic region of interest. For the first pass scintigrams, the segments were defined as in the right anterior oblique contrast angiograms, and for the gated blood pool scintigrams they were defined as in the axial left anterior oblique contrast angiograms. Thus each of the 10 angiographic segments had a corresponding scintigraphic segment that closely represented the same region of the left ventricle.

The ejection fraction for each scintigraphic segmet (segmental scintigraphic ejection fraction) was calculated as follows:

$$\text{Segmental scintigraphic ejection fraction} = [(\text{Segmental ED} - B_d) - (\text{segmental ES} - B_s)/(\text{segmental ED} - B_d)] \times 100,$$

where segmental ED = segmental end-diastolic counts, B_d = background normalized to the number of pixels in the segment at end-diastole, segmental ES = segmental end-systolic

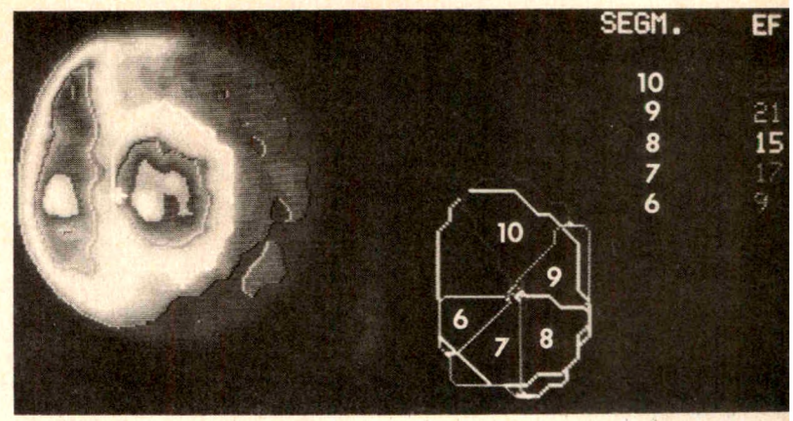

FIGURE 4. Superimposed end-diastolic and end-systolic left ventricular regions of interest of axial left anterior oblique gated scintigram in the same patient as in Figures 1 to 3. On the **right,** the regions of interest are divided into five segments (SEGM.) as described in the text, and the segmental scintigraphic ejection fraction (EF) is listed for each.

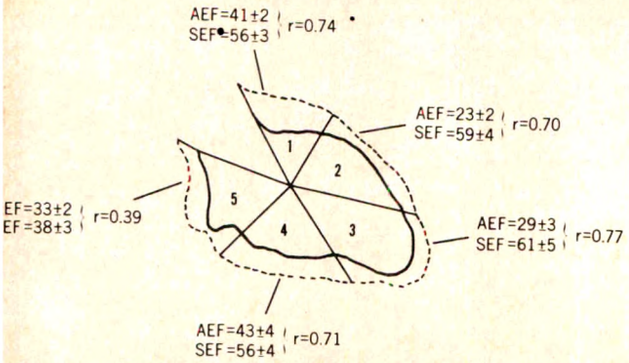

FIGURE 5. Correlation of the angiographic (AEF) and scintigraphic segmental ejection fractions (SEF) for right anterior oblique contrast ventriculograms and first pass scintigrams (mean ± standard error of the mean; n = 33). Values for segmental ejection fraction are shown as percent.

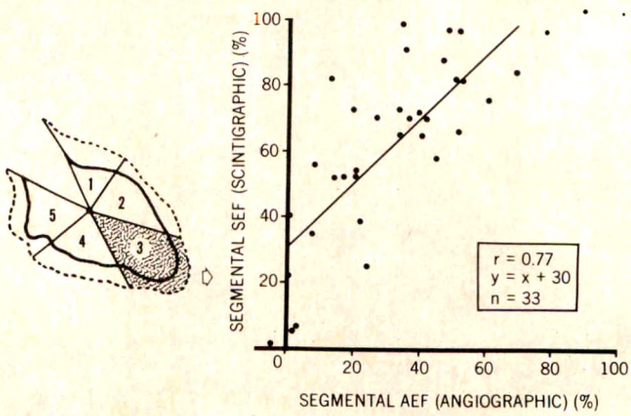

FIGURE 7. Correlation of the angiographic (AEF) and scintigraphic segmental ejection fractions (SEF) in apical segment 3.

counts, and B_s = background normalized to the number of pixels in the segment at end-systole.

Statistical analysis: Angiographic and scintigraphic ejection fractions are reported as mean percent ± standard error of the mean. Regression analysis was performed using the least squares method, and Student's paired *t* test was employed to assess the significance of differences between the observed linear regression analysis and the line of identity.

Results

Ejection fraction: Left ventricular ejection fraction obtained from biplane cineagiography (mean 45 percent, range 16 to 65) correlated well with ejection fraction calculated from first pass scintigraphy (r = 0.86, first pass ejection fraction = biplane angiographic ejection fraction + 5) and gated blood pool scintigraphy (r = 0.77, gated blood pool ejection fraction = 0.8 × biplane angiographic ejection fraction + 9).

Segmental ejection fraction: The correlation between segmental ejection fractions obtained from right anterior oblique contrast angiograms and first pass scintigrams in the 33 patients studied is depicted in Figure 5. A good correlation was found between angiographic ejection fraction and scintigraphic ejection fraction in the segments corresponding to the anterobasal (segment 1, r = 0.74), anterolateral (segment 2, r = 0.70), apical (segment 3, r = 0.77) and diaphragmatic (segment 4, r = 0.71) left ventricular regions. However, a very poor correlation was observed between angiographic and scintigraphic ejection fractions in the segment corresponding to the posterobasal left ventricular region (segment 5, r = 0.39). Figure 5 also shows that mean scintigraphic ejection fraction was considerably higher than the mean angiographic ejection fraction in segment 1 (56 ± 3 versus 41 ± 2 percent), segment 2 (59 ± 4 versus 23 ± 2 percent), segment 3 (61 ± 5 versus 29 ± 3 percent) and segment 4 (56 ± 4 versus 43 ± 4 percent).

The correlation between segmental ejection fractions obtained from axial left anterior oblique contrast angiograms and gated blood pool scintigrams is illustrated in Figure 6. A good correlation was present between angiographic and scintigraphic ejection fraction in the segments corresponding to the distal septal (segment 7, r = 0.66), posterolateral (segment 8, r = 0.71) and inferolateral (segment 9, r = 0.60) left ventricular regions. No correlation was found between the segments corresponding to the basal septal (segment 6, r = −0.02) and superolateral (segment 10, r = 0.05) regions. Mean scintigraphic ejection fraction was considerably higher than mean angiographic ejection fraction in all five segments: segment 6 (40 ± 3 versus 16 ± 5 percent), segment 7 (54 ± 4 versus 31 ± 3 percent), segment 8 (59 ± 5 versus 35 ± 5 percent), segment 9 (58 ± 4 versus 42 ± 3 percent) and segment 10 (46 ± 3 versus 30 ± 2 percent).

The best correlation between angiographic and scintigraphic ejection fractions was found in the apical region, corresponding to segment 3 in the right anterior oblique projection (Fig. 7). Although the correlation was good (r = 0.77), the linear regression line was significantly different ($p < 0.05$) from the line of identity, with scintigraphic ejection fraction equal to angiographic ejection fraction + 30, indicating consistently higher values for scintigraphic ejection fraction.

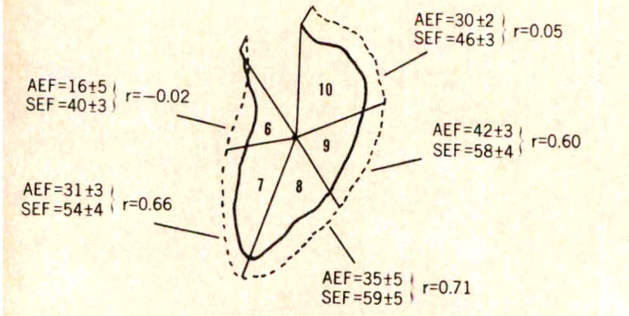

FIGURE 6. Correlation of the angiographic (AEF) and scintigraphic segmental ejection fractions (SEF) for axial left anterior oblique contrast ventriculograms and gated scintigrams (mean ± standard error of the mean; n = 33). Values for segmental ejection fraction are shown as percent.

Reproducibility of scintigraphic method: In order to assess the reproducibility of segmental scintigraphic ejection fraction, a second multiple gated left ventricular scintigram was performed in 13 randomly selected patients 2 hours after the initial study, with the gamma camera detector in the same axial left anterior oblique position. Since the segments corresponding to the basal septal (segment 6) and superolateral (segment 10) left ventricular regions correlated poorly with the corresponding angiographic segments, they were analyzed separately from the segments corresponding to the distal septal (segment 7), posterolateral (segment 8) and inferolateral (segment 9) regions. An excellent correlation ($r = 0.93$) was found between scintigraphic ejection fraction for segments 7, 8 and 9 on the first and second multiple gated studies, and the regression line (scintigraphic ejection fraction on second study = scintigraphic ejection fraction on first study + 5) did not differ significantly from the line of identity (intercept not different from 0, $p = 0.17$; slope not different from 1, $p = 0.30$). The reproducibility of segments 6 and 10 was considerably less, with $r = 0.63$ (scintigraphic ejection fraction on second study = 0.7 × scintigraphic ejection fraction on first study + 14).

To evaluate interobserver variability in the determination of segmental scintigraphic ejection fraction, 10 multiple gated left ventricular scintigrams were processed independently by two experienced operators. Interobserver variability was minimal, with excellent agreement between the two operators for segments 7, 8 and 9 ($r = 0.98$; scintigraphic ejection fraction by second operator = scintigraphic ejection fraction by first operator − 0.6). Interobserver variability was considerably greater for segments 6 and 10 ($r = 0.79$; scintigraphic ejection fraction by the second operator = 0.6 × scintigraphic ejection fraction by the first operator + 14).

Discussion

Regional left ventricular function in coronary artery disease: Regional left ventricular dysfunction is common in patients with coronary artery disease, and its extent and severity have important prognostic and therapeutic implications.[28–30] Recently, the development or worsening of regional left ventricular dysfunction during exercise has been shown to be a sensitive indicator of hemodynamically significant coronary stenoses.[4–7,31] However, subjective analysis of contrast and radionuclide left ventricular angiograms, is characterized by significant inter- and intraobserver variability,[8–11] and objective quantitative evaluation of regional ventricular function is essential in these patients. Techniques used to assess regional left ventricular function from contrast angiograms have been applied to the analysis of radionuclide angiograms.[5,17–19] These techniques, usually based on fractional changes in radii, hemiaxes or area, require reliable detection of left ventricular boundaries, often hampered by the miniature display and indistinct edges of radionuclide angiograms. In addition, scintigraphic studies provide recording of three dimensional radioactivity from the left ventricular cavity, information that is lost when bidimensional angiographic techniques are used to analyze regional left ventricular function from left ventricular scintigrams.

Quantitative assessment of regional left ventricular function: In the present study, we employed biplane axial left ventricular cineangiography (45° right anterior oblique and 60° left anterior oblique projection, 25° caudocranial angulation). These angiographic views are used routinely at our institution and have been shown to improve the evaluation of regional left ventricular wall motion without compromising left ventricular volume quantitation.[20] These angiographic projections, although not identical, were similar to the views employed in the first pass and gated left ventricular scintigrams. Previous work in our laboratory[22] has shown that segmental left ventricular wall motion can be accurately assessed from contrast cineangiograms by fractional changes in area of segments defined by radial lines originating from the center of mass of the end-diastolic left ventricular silhouette. In this study, we used the same method to divide the left ventricular regions of interest in the first pass and gated left ventricular scintigrams in five segments each. Therefore, it appeared reasonable to expect that corresponding angiographic and scintigraphic segments closely represented the same region of the left ventricle.

We found a good correlation between angiographic and scintigraphic segmental ejection fraction in the anterobasal, anterolateral, apical, diaphragmatic, distal septal, posterolateral and inferolateral left ventricular segments. Despite these good correlations, the mean values for segmental scintigraphic ejection fraction were consistently higher than the mean values for segmental angiographic ejection fraction (Fig. 5 to 7). Our method for quantitative analysis of regional left ventricular function by contrast angiography was based on changes in area as determined with planimetry and thus was only able to characterize wall motion in that portion of the left ventricular wall tangential to the X-ray beam. This method did not provide any information regarding the function of the neighboring myocardium that did not form a border with the X-ray beam. In contrast, segmental scintigraphic ejection fraction was derived from changes in end-diastolic and end-systolic counts in each segment, and thus should reflect segmental changes in blood volume influenced not only by the function of the border-forming portion of myocardial wall, but also by the function of nonborder-forming myocardium and probably by the function of neighboring segments. Although a myocardial depressant effect of sedatives and contrast medium during cardiac catheterization cannot be excluded as a factor in the lower values for segmental angiographic ejection fraction, the consistently higher values for segmental scintigraphic ejection fraction were expected as a reflection of changes in volume (cubic function) compared with changes in area (squared function). This represents a theoretical advantage of scintigraphy compared with angiography in the evaluation of regional left ventricular function.

The correlation between segmental angiographic and scintigraphic ejection fraction was very poor or nonexistent in segments 5, 6 and 10. This inadequate correlation, in addition to the rather poor reproducibility of these segments (6 and 10), was probably related to the difficulty in defining the mitral and aortic valve planes and high septum with radionuclide left ventricular angiocardiograms obtained in the right anterior oblique and axial left anterior oblique projections. Furthermore, any overlap between the left atrium and left ventricle in the axial left anterior oblique projection would affect end-diastolic and end-systolic counts in segment 10, but not necessarily the area of the corresponding angiographic segment. These observations are in agreement with those of other investigators[32] who have been unable to assess accurately the performance of the basilar left ventricular regions with gated blood pool scintigraphy in the left anterior oblique view.

Quantitative assessment of global left ventricular function: We also found a good correlation between global angiographic and scintigraphic left ventricular ejection fraction in the 33 patients studied. The correlation was better for first pass ($r = 0.86$) than for gated blood pool ($r = 0.77$) scintigraphy, and this may also be partly related to overlap between the upper and posterior portion of the left ventricle and left atrium in the axial left anterior oblique projection, so that this nonventricular source of radioactivity reaching the detector could result in greater error in the calculation of ejection fraction than that of studies performed in the right anterior oblique projection. In addition, background radioactivity is proportionately greater in gated than in first pass studies, and a small error in estimation of background would result in a proportionately greater error in the calculated ejection fraction.

Clinical implications: This study demonstrates that determination of segmental scintigraphic ejection fraction obtained from first pass and multiple gated blood pool left ventricular scintigrams performed in the right anterior oblique and axial left anterior oblique projections enables quantitative evaluation of the function of the anterobasal, anterolateral, apical, diaphragmatic, distal septal, posterolateral and inferolateral left ventricular regions with high reproducibility and minimal interobserver variability. Segmental scintigraphic ejection fraction can easily be obtained from radionuclide angiocardiograms and may be useful in precisely detecting and quantitating resting or exercise-induced regional left ventricular dysfunction, and thus aid in the noninvasive diagnosis of coronary disease. Additionally, it may prove useful in quantitating infarct size, monitoring the natural history of these patients, and evaluating changes resulting from physiologic, pharmacologic, metabolic and surgical interventions.

Intravenous Xenon-133 for the Determination of Radionuclide First Pass Right Ventricular Ejection Fraction

MARK J. GOLDBERG, MD
JOSEPH MANTEL, PhD
MARK FRIEDIN, MS
ROBERT RUSKIN, MD
MELVYN RUBENFIRE, MD, FACC

The use of intravenous xenon-133 for determination of radionuclide first pass right ventricular ejection fraction is described. First pass determinations of right ventricular ejection fraction were made with both xenon-133 and technetium-99m in 13 subjects (15 right ventricular ejection fraction determinations); results obtained with xenon-133 show an excellent correlation ($r = 0.98$, $p < 0.002$) with results obtained using technetium-99m. Because of rapid pulmonary elimination of xenon-133 from the body, the use of this radioisotope allows multiple first pass right ventricular ejection fraction determinations within a short period of time, without significant radiation exposure for the patient.

Radionuclide techniques have found widespread clinical application in recent years in the noninvasive assessment of left and right ventricular function. The radionuclide ejection fraction of the left ventricle can be measured by either the first pass or gated equilibrium method and correlates well with contrast angiographic methods.[1] Radionuclide right ventricular ejection fraction has been determined generally by the first pass technique, using a radiopharmaceutical containing technetium-99m.[2,3] Poor delineation of right ventricular borders has made quantitation of the right ventricular ejection fraction by the gated equilibrium method difficult, although two techniques employing the gated equilibrium method were recently reported.[4,5]

So that the patient will not be exposed to an excessive dose of radiation, a total of no more than 20 to 25 mCi of technetium-99m is administered during a radionuclide study, limiting the number of first pass radiopharmaceutical injections to two or less. The accumulation of background activity after two bolus injections of technetium-99m, which markedly affects the accuracy of any subsequent first pass ejection fraction determinations, also precludes more than two first pass injections on a given day. These considerations limit the usefulness of technetium-99m in determining first pass right ventricular ejection fraction in critical care situations where frequent, repeated studies are required.

We describe the use of intravenous xenon-133 with the first pass technique for right ventricular ejection fraction determination. Because the isotope is eliminated from the body rapidly through the lungs, the radiation dose is negligible compared with that associated with technetium-99m,[6] and background activity does not accumulate with successive injections; thus, multiple bolus injections of the isotope can be made, allowing serial studies of right ventricular ejection fraction within a short period with no additional radiation exposure for the patient.

Methods

Study subjects: Thirteen subjects were studied (Table I). Three were normal volunteers, and the remaining 10 were patients with the following clinical

diagnoses: coronary artery disease with angina pectoris (4 patients), acute myocardial infarction, predominantly right ventricular (1 patient), congestive heart failure (3 patients), pulmonary hypertension (1 patient) and chronic obstructive pulmonary disease with cor pulmonale (1 patient).

Radionuclide imaging: Fifteen to 20 mCi of xenon-133 dissolved in 2 cc of saline solution, supplied in Carpules® (Mallinckrodt, Inc., St. Louis, Missouri), was transferred into a 3 cc glass syringe using a Carpule aspirator (Cook-Waite Laboratories, Inc., New York, New York); the Carpules contained 25 mCi of xenon-133 at the time of shipment, before radioactive decay. The contents of the syringe were injected rapidly as a bolus dose through a large antecubital vein using an indwelling Teflon® catheter (except in the patient with acute right ventricular infarction, in whom the radioisotope was injected directly into the right atrium through the proximal lumen of an indwelling Swan-Ganz thermodilution catheter). The bolus injection was followed with a 10 cc saline flush. Exhaled xenon was collected in a commercially available, mobile charcoal trap to assure that no xenon would escape into the environment and contaminate personnel.

The first transit of the radioactive bolus dose through the central circulation was recorded in the 30° right anterior oblique projection. For 10 of the 13 patients, a single crystal Anger gamma scintillation camera (Searle LFOV) equipped with a general purpose low energy parallel hole collimator was used, and data were acquired in list mode by a digital computer (NOVA computer, with MDS system). For the remaining three patients, a single crystal Anger gamma scintillation camera equipped with a high sensitivity low energy parallel hole collimator was used, and data were acquired in frame mode, 33 frames/s, by a digital on-board computer (Ohio Nuclear Sigma 420 with a VIP 550 on-board computer). For xenon-133 injections the gamma scintillation camera was set at a photopeak of 80 keV with a 20 percent window.

Calculation of right ventricular ejection fraction: The imaged data were replayed and a region of interest was assigned to the right ventricular blood pool, with the right atrium and pulmonary artery excluded from this region of interest, according to the method of Tobinick et al.[3] A second region of interest was assigned to noncardiac background structures. Time-activity curves were then generated from both the right ventricular and background regions of interest. Generally, peak right ventricular count rates ranged from 100 to 600 counts; these count rates corresponded to 33 ms time intervals when the Ohio Nuclear Sigma 420 camera with VIP computer was used, and 60 to 80 ms intervals when the Searle LFOV camera was used, depending on the heart rate. Background activity was minimal in comparison, with the average count rate 5 to 20 counts per time interval. After correcting the right ventricular time-activity curve for background ac-

TABLE I
Right Ventricular Ejection Fraction (RVEF) Values Obtained With Technetium-99m and Xenon-133 Techniques

Clinical Diagnosis	RVEF ^{99m}Tc	RVEF ^{133}Xe
Normal volunteer	0.41	0.41
Normal volunteer	0.47	0.51
Normal volunteer	0.36	0.38
CAD, angina	0.58	0.60
CAD, angina	0.47	0.53
CAD, angina	0.44	0.48
CAD, angina	0.45	0.44
AMI, predominantly RV		
Initial	0.13	0.13
3 weeks later	0.12	0.13
Congestive heart failure	0.53	0.50
Congestive heart failure	0.22	0.17
Congestive heart failure	0.54	0.56
Pulmonary hypertension	0.34	0.36
COPD with cor pulmonale		
Before isoproterenol	0.39	0.45
After isoproterenol	0.38	0.43

AMI = acute myocardial infarction; CAD = coronary artery disease; COPD = chronic obstructive pulmonary disease; RV = right ventricular; ^{99m}Tc = values determined with technetium-99m technique; ^{133}Xe = values determined with xenon-133 technique.

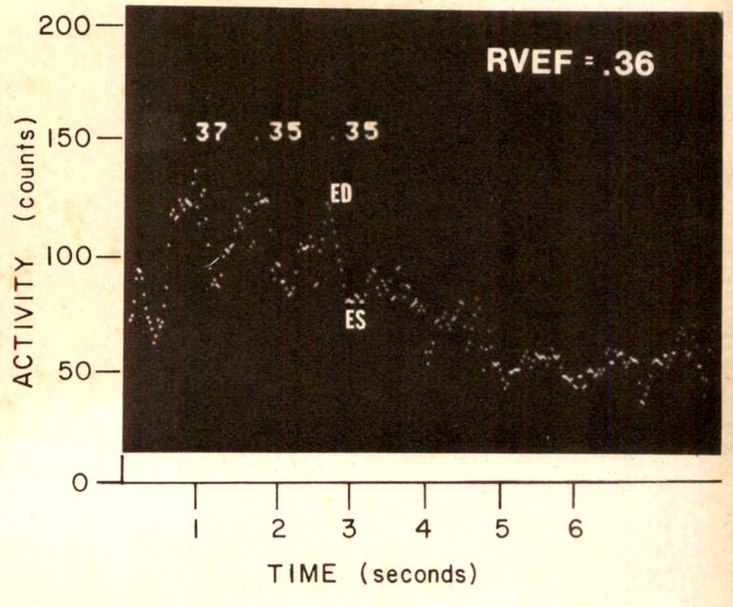

FIGURE 1. Background-corrected right ventricular time-activity curve using xenon-133. Each point represents the activity during a 33 ms interval (33 curve points/s). Right ventricular ejection fraction (RVEF) is calculated by dividing the difference in counts between end-diastole (ED) and end-systole (ES) by the number of counts at end-diastole for each beat. The average right ventricular ejection fraction for the three analyzed beats is 0.36.

tivity by subtracting the background time-activity curve, ejection fraction was calculated by dividing the difference in counts between end-diastole and end-systole (a value proportional to the stroke volume) by the number of counts at end-diastole (a value proportional to the end-diastolic volume). Only beats from the early downslope of the right ventricular time-activity curve were used for calculation. In general, two or three cardiac cycles were used for determining the ejection fraction and the values from the analyzed beats were averaged (Fig. 1).

Comparison with technetium-99m: In order to compare the new method with standard techniques, the same procedure was repeated using 10 to 15 mCi of technetium-99m–labeled human serum albumin instead of xenon-133 10 minutes after the xenon-133 injection. The 30° right anterior oblique projection was again utilized; the gamma scintillation camera used for the preceding xenon-133 injection in a particular patient was used for the corresponding technetium-99m injection, and the camera was set at a photopeak of 140 keV with a 20 percent window. Right ventricular ejection fraction was calculated in an identical fashion. In the patient with chronic obstructive pulmonary disease, injections of both radioisotopes were repeated after the sublingual administration of isoproterenol; in the patient with acute right ventricular infarction, studies were repeated 3 weeks after the initial studies. Thus right ventricular ejection fraction was determined 15 times in 13 subjects using each radioisotope.

Results

The radionuclide first pass right ventricular ejection fraction values determined with the technetium-99m and xenon-133 techniques for each of the 13 subjects studied are shown in Table I. In Figure 2, right ventricular ejection fraction determined with xenon-133 is plotted against right ventricular ejection fraction determined with technetium-99m for the 15 right ventricular ejection fraction determinations. The correlation coefficient is r = 0.98 ($p < 0.002$).

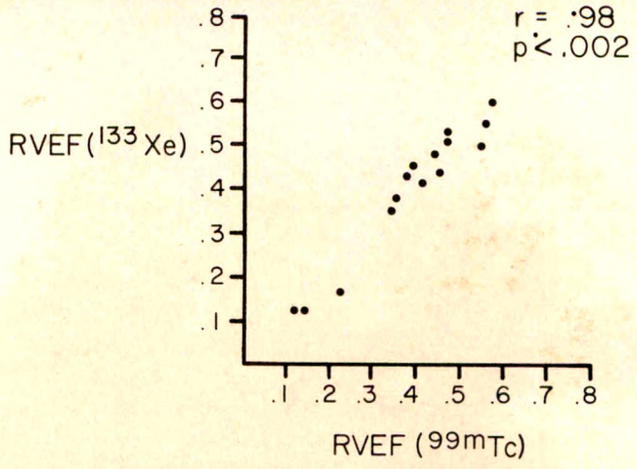

FIGURE 2. Right ventricular ejection fraction (RVEF) by the xenon-133 technique versus that by the technetium-99m technique.

Discussion

Right ventricular ejection fraction: clinical role: First pass radionuclide determination of right ventricular ejection fraction using technetium-99m has been employed to study right ventricular function in normal subjects and in patients with chronic obstructive pulmonary disease, pulmonary hypertension secondary to mitral or aortic valve disease, acute myocardial infarction and angiographically documented coronary artery disease.[2,3,7–12] Right ventricular ejection fraction is usually abnormal in patients with cor pulmonale secondary to chronic obstructive pulmonary disease, but it varies widely and may be normal in patients with chronic obstructive pulmonary disease without evidence of corpulmonale.[7,8] Impaired right ventricular ejection fraction is usually restored to normal after surgical relief of pulmonary hypertension in patients with mitral or aortic valve disease.[9] First pass determination of right ventricular ejection fraction has been useful in the identification of patients with inferior wall myocardial infarction who have associated right ventricular infarction.[3,9,10] Exercise studies in patients with angiographically documented coronary artery disease have yielded conflicting results: Johnson et al.[11] found that stenotic lesions of the proximal right coronary artery are associated with no change in the first pass right ventricular ejection fraction during exercise, whereas coronary artery disease not involving the proximal right coronary artery is associated with an increase in right ventricular ejection fraction during exercise. In contrast, Berger et al.[12] reported that the major determinant of the right ventricular ejection fraction response to exercise in patients with coronary artery disease is the concomitant left ventricular ejection fraction response to exercise, rather than the presence or absence of stenosis of the proximal right coronary artery.

Limitations of gated equilibrium techniques using technetium-99m: Two gated equilibrium techniques for right ventricular ejection fraction were described recently, one employing separate end-diastolic and end-systolic regions of interest[4] and the other using a single fixed end-diastolic region of interest[5]; both methods involve the use of technetium-99m. Although these techniques offer the possibility of serial measurement of right ventricular ejection fraction within a short period of time, they have potential limitations. In patients with severe right ventricular failure and marked right atrial enlargement, overlap between the right ventricle and right atrium will be seen in the left anterior oblique view even at end-systole, precluding clear separation of these structures when the right ventricular region of interest is assigned.[4] Difficulty in separating the pulmonary outflow tract from the body of the right ventricle can also be encountered in gated equilibrium determination of right ventricular ejection fraction.[5] Inability to exclude the right atrium and pulmonary outflow tract when assigning the right ventricular region of interest tends to make the gated equilibrium right ventricular ejection fraction lower than that determined by first pass studies.[5] Another disadvantage of the gated equilibrium techniques for right ventricular ejection fraction compared with first

pass studies is that at least 2 minutes of imaging time is required for the former, whereas the latter requires 30 seconds or less; this difference in data collection time can be important when acutely ill patients are studied or when interventions involving rapidly changing states are evaluated.

Xenon-133 for determination of radionuclide right ventricular ejection fraction: Xenon-133 is a chemically inert gas. It is produced by fission of uranium-235 and decays to cesium-133 with emission of gamma rays of 81 keV (33 percent). Xenon-133 has a physical half-life of 5.3 days and a biologic half-life of 1 to 2 minutes, the latter due to almost complete elimination of the radioisotope from the body in one passage through the lungs.[13] Only 5 percent of an injected intravenous dose of xenon-133 reaches the systemic circulation.[14]

By inhalation and intravenous injection, xenon-133 has been used in pulmonary ventilation studies.[15–17] Dissolved in saline solution and injected intraarterially, the radioisotope has been employed in the study of myocardial blood flow.[14,18] With constant infusion into the left ventricle, the use of xenon-133 for the quantitation of mitral regurgitation has been described.[19] In the present study, the use of intravenous xenon-133 for determination of first pass radionuclide right ventricular ejection fraction is described for the first time. Right ventricular ejection fraction determinations using xenon-133 showed an excellent correlation ($r = 0.98$, $p < 0.002$) with the results obtained using technetium-99m.

Advantages of xenon-133 technique: The advantages of using xenon-133 rather than technetium-99m in first pass determination of right ventricular ejection fraction are related to the rapid pulmonary elimination of the radioisotope: (1) The patient is exposed to a much lower radiation dose (less than 1/100 the radiation dose for a first pass bolus dose using technetium-99m,[6] and (2) background activity does not accumulate with successive bolus injections, as it does with technetium-99m. These factors allow multiple bolus injections and thus multiple first pass determinations of right ventricular ejection fraction in a patient within a short period. This feature is important in the critical care setting, where serial measurements of right ventricular ejection fraction involving extremely short imaging times can be made using xenon-133 before and after various interventions, and can provide potentially valuable information. One promising application of the xenon-133 technique for first pass right ventricular ejection fraction is in patients with acute myocardial infarction, predominantly right ventricular, complicated by cardiogenic shock: Serial first pass studies of right ventricular ejection fraction can supplement hemodynamic data in following the response to various therapeutic interventions such as administration of inotropic agents or intraaortic balloon pump counterpulsation.

Disadvantages of xenon-133 technique: The main disadvantage of xenon-133 at present is its cost. Because of little demand for its use, the amount of radioisotope necessary for one first pass injection costs approximately 16 times as much as an equivalent amount of technetium-99m. The rapid pulmonary elimination of xenon-133 is a second disadvantage: The lack of appearance of the radioisotope in significant concentration in the left ventricle in patients without a right to left shunt precludes determination of the left ventricular ejection fraction from the same first pass bolus injection.

In conclusion, the use of intravenous xenon-133 for measurement of radionuclide first pass right ventricular ejection fraction provides results that show an excellent correlation with values obtained using technetium-99m and offers the possibility of performing multiple first pass tests in a patient with no significant increase in radiation exposure.

TAKE A LOOK AT HONEYWELL'S NEW RECORDER AND SEE WHAT YOU'VE BEEN MISSING IN ECHOCARDIOGRAMS.

If you're not seeing everything you expect from your present system, you should be looking at the LS-8—a totally new concept in presenting diagnostic information for echocardiography.

It delivers crisp black and white echocardiograms that won't fade. Echocardiograms that are developed dry, without chemicals, and without any warm-up delay caused by speed changes. So you get an instant echocardiogram for immediate evaluation.

And what an echocardiogram! Sharp and clear, with automatic intensity compensation for paper speeds from 5 to 100 mm/sec and the kind of high resolution and superior contrast that comes only from a wide and accurate gray scale range. Optional with direct print paper at 5 to 500 mm/sec.

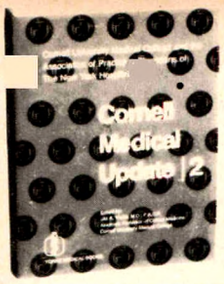
Specific application modules provide optimum performance in a wide variety of applications, including M-mode echo, video for real time, and B-scan. Other modules can interface with up to six physiological data channels and provide timelines. The 2 kHz frequency response of the data channels provides diagnostic-quality phonocardiography recordings. And since the LS-8 is convection-cooled, there's no fan noise, no acoustical interference on sensitive phonocardiography channels.

Now add operation that's simpler than ever, a design that's quick and easy to service, and you have the LS-8, backed by the experience and expertise of people whose business is graphic recorder technology.

Honeywell's new LS-8 Stripchart Recorder will deliver every bit of image quality your ultrasound system is capable of. Ask your echo system supplier. Or contact Bob Shipman, Honeywell Test Instruments Division, Dept. AJC, Box 5227, Denver, Colorado 80217, phone 303/773-4700.

WE'LL SHOW YOU A BETTER WAY.

Honeywell



Now in book form...the latest **Update Your Medicine** lectures

CORNELL MEDICAL UPDATE/2

Edited by LILA A. WALLIS, MD, FACP

Helps you keep up with the new advances in your specialty in the comfort of your home or office.

All new material—specialties expanded.

The workbook format of CORNELL MEDICAL UPDATE/2 breaks medical publishing traditions by giving practicing physicians a quick overview of the latest advances in their specialty. It transcribes the Update Your Medicine lectures sponsored by New York Hospital-Cornell Medical Center. These lectures are well-known for helping physicians prepare for Recertification despite the demands of a heavy practice.

The new approach of the first volume was so well-received that it went through three printings in less than two years. Now the just published CORNELL MEDICAL UPDATE/2 takes up where the first volume left off. It has been specially designed for the practicing physician who has difficulty keeping up with the growing literature of the field. Each chapter transcribes one of the lectures and covers a specific speciality in-depth from basic physiologic and chemical principles to its clinical applications.

Lila A. Wallis, MD, FACP, the series editor, has eliminated all the filler material a *continuing* education does not need. You won't find historical reviews or a rehash of material you've known since medical school. You will find the practical, life-saving knowledge a dynamic practice depends on. Because the lectures have been edited for easy reading and laid out for quick comprehension, you'll be able to incorporate all the material into your own professional technique.

Earn 25 Credits Towards AMA Physician's Recognition Award. CORNELL MEDICAL UPDATE/2 has been approved for Category 1 credit towards the AMA's Physician's Recognition Award for Continuing Medical Education. Full details on how to apply for credit are included with every copy.

Yorke Medical Books, 666 5th Ave., N.Y., N.Y. 10103 AJC 3/81

Please send me a copy of CORNELL MEDICAL UPDATE/2 at $38.00. I may use the book for 30 days and if not completely satisfied, return it for full refund or credit.

Danger!
PVC's don't sleep!

324 mg
Quinaglute®
DURA-TABS®
(quinidine gluconate)

CONTRAINDICATIONS:
Aberrant impulses and abnormal rhythms due to escape mechanisms should not be treated with quinidine.

Partial A-V or complete heart block, or intraventricular conduction defects, especially those exhibiting a marked grade of QRS widening.

Renal disease resulting in significant azotemia, or those developing cardiotoxic effects such as conduction defects, ventricular premature beats, ventricular tachycardia or flutter while on the drug.

Marked cardiac enlargement, particularly with congestive failure, poor renal function, and especially renal tubular acidosis.

Idiosyncrasy or hypersensitivity to quinidine.

WARNINGS:
In the treatment of atrial flutter, reversion to sinus rhythm may be preceded by a progressive reduction in the degree of A-V block to a 1:1 ratio resulting in an extremely rapid ventricular rate.

PRECAUTIONS:
The precautions to be observed include all those applicable to quinidine. A preliminary test dose of a single tablet of quinidine sulfate should be administered to determine if the patient has an idiosyncrasy to quinidine. Hypersensitivity to quinidine, although rare, should constantly be considered, especially during the first weeks of therapy.

Quinidine in large doses may reduce the contractile force of the heart, therefore, extreme caution should be exercised in using the drug in patients with severe heart disease, hypotension or digitalis intoxication. The potential disadvantages and benefits must be weighed.

It should be administered cautiously, if at all, to senile patients.

Hospitalization for close clinical observation, electrocardiographic monitoring, and possibly plasma quinidine levels is indicated when large doses are used or with patients who present an increased risk.

ADVERSE REACTIONS:
Symptoms of cinchonism, ringing in ears, headache, nausea, disturbed vision may appear in sensitive patients after a single dose of the drug.

Cardiovascular: Widening of QRS complex, cardiac asystole, ventricular ectopic beats, idioventricular rhythms including ventricular tachycardia and fibrillation, paradoxical tachycardia, arterial embolism, hypotension.

Gastrointestinal: Nausea, vomiting, abdominal pain, diarrhea.

Hematologic: Acute hemolytic anemia, hypoprothrombinemia, thrombocytopenic purpura, agranulocytosis.

Central Nervous System: Headache, fever, vertigo, apprehension, excitement, confusion, delirium and syncope, disturbed hearing (tinnitus, decreased auditory acuity), disturbed vision (mydriasis, blurred vision, disturbed color perception, reduced vision fields, photophobia, diplopia, night blindness, scotomata), optic neuritis.

Dermatologic: Cutaneous flushing with intense pruritus.

Hypersensitivity Reactions: Angioedema, acute asthmatic episode, vascular collapse, respiratory arrest.

See package insert for full information.

...the most comprehensive study of...the most fascinating syndrome in Cardiology...

THE PRE-EXCITATION SYNDROME: FACTS AND THEORIES

Libi Sherf, MD, FACC
Assoc. Professor of Cardiology, Heart Institute, Chaim Sheba Medical Center, Tel Hashomer, University of Tel Aviv—Sackler School of Medicine, and Visiting Assoc. Professor, Dept. of Medicine, University of Alabama.

Henry N. Neufeld, MD, FACC
Professor of Medicine and Chaim Sheba Professor of Cardiology, Chief, Heart Institute, Chaim Sheba Medical Center, Tel Hashomer, University of Tel Aviv—Sackler School of Medicine.

Every cardiologist, internist, pediatrician, surgeon—indeed, *every physician*—should have a good basic knowledge of the Pre-excitation Syndrome. Here are just a few reasons why this is so essential:

- ☐ ⅓ of all pre-excitation cases are misdiagnosed.
- ☐ 5% to 10% of all tachycardias in adults are produced by pre-excitation.
- ☐ In ½ of all infants under 10 months of age with life-threatening tachycardias, the tachycardias are actually secondary to pre-excitation.
- ☐ ⅓ to ½ of all children with pre-excitation have an additional heart disease.

Starting with Wolff, Parkinson and White's classic paper, this book gives a comprehensive summary of all important facts of pre-excitation, plus the authors' personal experiences of follow-up studies of patients through many decades. It also brings a broad view of the literature and discusses the different structural and physiological aspects which form the pathomechanism of pre-excitation.

"What is offered richly in this book is a methodical and comprehensive analysis of virtually all currently available knowledge on the subject. This is done with an admirable even-handedness, dealing objectively with all viewpoints but at the same time evaluating relative strengths and weaknesses of each observation and hypothesis. There is brought a wisdom here which only time and experience can provide. The encyclopedic references alone would make the book invaluable to anyone seriously interested in the Wolff-Parkinson-White syndrome. But when knowledgeable discussion and personal observations are added, it is genuinely a monumental contribution to clinical cardiology and cardiac electrophysiology."

Thomas N. James, MD
The Mary Gertrude Waters Professor of Cardiology and Chairman of the Department of Medicine, The University of Alabama in Birmingham, and Physician-in-Chief, University of Alabama Hospitals.

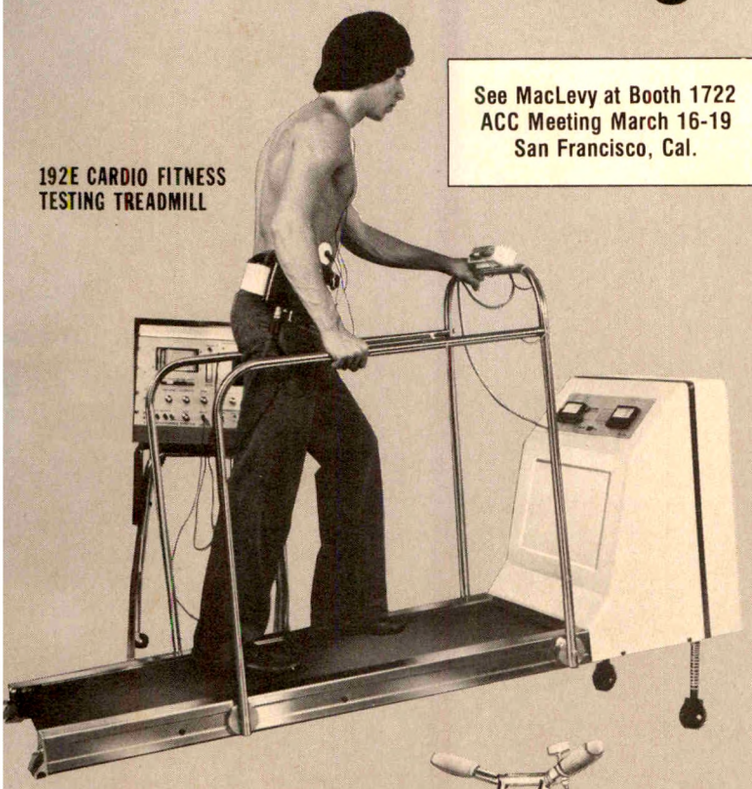
CARDIO FITNESS TESTING
Treadmills and Ergometer Cycles



192E CARDIO FITNESS TESTING TREADMILL

See MacLevy at Booth 1722
ACC Meeting March 16-19
San Francisco, Cal.

Cardio Fitness Testing Treadmills

Treadmills designed for Professional, Commercial and Home use ... at a surprisingly low cost!

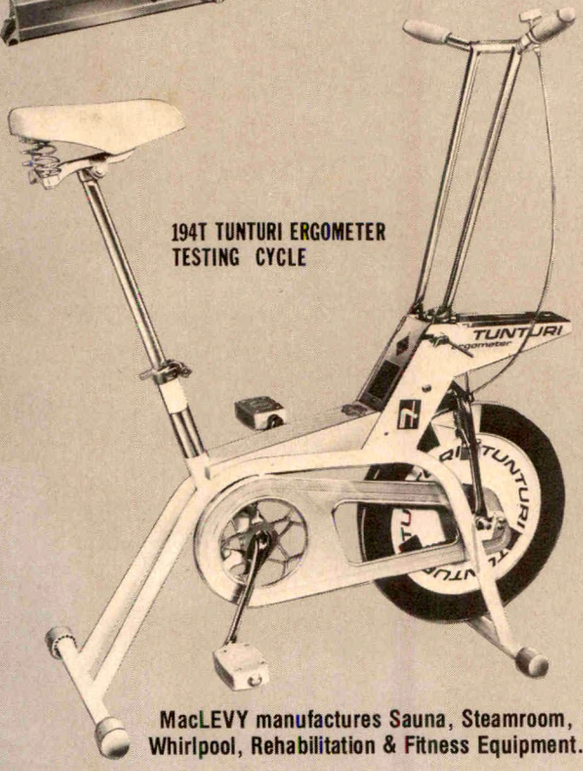
20 Different standard models to meet the differing needs of Physicians, Hospitals and Testing Facilities.

- Compatible with all monitoring equipment.
- Speed choice - 0.5 to 10 Miles per hour - for Pulmonary labs and Vascular programs.
- Grade elevation from 0% to 25 %.
- Gradual, controlled change of speed and elevation.
- Available with Console mounted, Front Rail mounted or Remote Controls.
- Precision Readout Meters.
- Quiet operation.

Tunturi Ergometer Tesing Cycles

The Tunturi Ergometer combines the advantages of a bicycle exerciser with those of an ergometer tester. It permits physiological measurements to be taken during exercise periods. Physicians recommend this unit for use by patients who require carefully controlled exercise.

- Built-in Speedometer/Tachometer & Odometer.
- 36 Pound Flywheel for Smooth Stable Operation.
- Disc Type Resistance System.
- Adjustable Seat and Handlebars.



194T TUNTURI ERGOMETER TESTING CYCLE

MacLEVY manufactures Sauna, Steamroom, Whirlpool, Rehabilitation & Fitness Equipment.

MacLevy SINCE 1893

"Hello, Clinical Data!?...when we cancelled your Holter service last year to go to a cheaper service?... well...we...I was wondering if..."

We call it the "lowest bidder syndrome."

The Problem.
Subscribing to a Holter service by calculator rather than quality.

The Symptoms.
Paying less... and getting less.

Less recording capability. Due to artifact prone recorders. Recharged batteries that really ought to come with jumper cables. And patient cables you wouldn't use to string twinkle lights on your Christmas tree.

Less reviewing capability. Due to skeleton crews, fewer shifts, and the use of flickering superimposition techniques that could make any technician run to a disco just to rest her eyes.

Less reporting quality. Due to unsubstantiated ectopic summaries (which may be automatically generated).

Because of fewer tracings in support of reported abnormalities. And because of presentation formats that can be harder to read (and pronounce) than Dostoyevski in Hindustani.

The Cure.
Choose Clinical Data, and stay with Clinical Data. Get more, and more, and more... of More.

More recording capability. Because of an FM recorder that is less prone to artifact. And that uses one-time-only disposable batteries.

More reviewing capability. Because of our many reviewing systems that operate 24-hours a day, seven days a week. Because of our own Stein/Peterson™ Technique in which the *entire recording* is presented in consecutive two-minute segments on a 19-inch screen at a rate controlled by the examiner.

More reporting capability. Because of a report that includes standard ECG strips, hourly heart rate, and graphic and numerical quantitation of up to eight different ectopic foci validated by the examiner.

More quality control. Because each report is reviewed before it is delivered, and because our separate Q.C. department routinely checks each examiner.

Even if you've seen one of Clinical Data's LCG Reports, you haven't really seen one of Clinical Data's *new* LCG Reports. We've made the best even better. Call or write. We'll send you one.

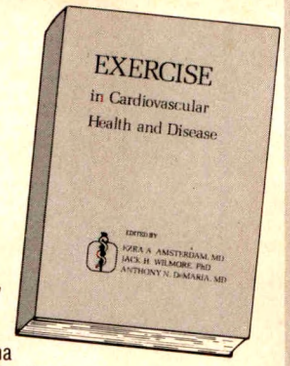
For **every** professional with an

nterest in Exercise and the Heart.

EXERCISE
n Cardiovascular
Health and Disease



Edited by
Ezra A. Amsterdam, MD, Chief Coronary Care Unit, Univ. of Calif. School of Medicine
Jack H. Wilmore, PhD, Professor and Head Dept. of Physical Education & Athletics, Univ. Arizona
Anthony N. DeMaria, MD, Dir. Echocardiography Section, Univ. of Calif. School of Medicine

SEPTEMBER 1977, 408 PAGES, ILLUS. $33.00

This comprehensive work covers every aspect of exercise and its role in **Diagnosis, Treatment,** and **Prevention** of cardiac disease.

The scope of EXERCISE IN CARDIOVASCULAR HEALTH AND DISEASE is so broad that it goes from something as basic as a detailed study of the heart muscle itself to the latest advances in cardiac rehabilitation.

Special attention is given to such subjects as:

- ☐ Present status of exercise testing and training in terms of physiological bases and clinical applications
- ☐ Nuclear cardiology
- ☐ Computer analysis of the exercise ECG
- ☐ Stress myocardial scintigraphy
- ☐ Various interpretations of exercise tests in the asymptomatic population

The editors have brought together a distinguished group of specialists—all of whom have made major contributions to the field. Included are outstanding scientists, clinicians, exercise physiologists, and physical educators.

For you who have any interest—professional or personal—in exercise and the heart, we urge you to *look* at a copy of EXERCISE IN CARDIOVASCULAR HEALTH AND DISEASE. That's right! You're invited to *look* it over before buying it.

Send for your copy of Exercise in Cardiovascular Health and Disease today. *Then use it for 30 days without risk.*

"The list of contributors bespeaks its authority: outstanding physicians in cardiovascular medicine and distinguished physical educators . . . No serious student or practitioner in the field would wish to be without this remarkably thorough account . . ."

David H. Spodick, MD, St. Vincent Hospital, Worcester, Mass. in ***The Journal of the American Medical Assoc.,*** *June 16, 1978, Vol 239, No. 24*

"Many areas in this field which have not as yet been addressed under one cover and a few rather unique ones are mentioned . . . an important synthesis of our current knowledge in the field."

Harold T. Mankin, MD, Division of Cardiovascular Diseases and Internal Medicine, ***Mayo Clinic Proceedings,*** *May 1978*

LOPRESSOR®
metoprolol tartrate

***Metoprolol exerts a relative preference for beta-one receptors.**

Works where it should– not where it shouldn't– in hypertension

Lopressor represents a refinement in beta-blocker control of hypertension. Only Lopressor exerts a relatively selective effect on beta-one receptors in the heart—those involved in lowering blood pressure—at usual therapeutic levels.

Please see next page for brief summary of prescribing information.

Geigy

Lopressor®
metoprolol tartrate

An antihypertensive
beta-blocking agent

Brief Summary of Prescribing Information

Indications Lopressor is indicated in the management of hypertension. It may be used alone or in combination with other antihypertensive agents, especially thiazide-type diuretics.

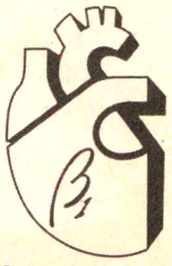
Contraindications Lopressor is contraindicated in sinus bradycardia, heart block greater than first degree, cardiogenic shock, and overt cardiac failure (see **Warnings**).

Warnings ***Cardiac Failure:*** Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure, and beta blockade carries the potential hazard of further depressing myocardial contractility and precipitating more severe failure. In hypertensive patients who have congestive heart failure controlled by digitalis and diuretics, Lopressor should be administered cautiously. Both digitalis and metoprolol slow AV conduction.

In Patients Without a History of Cardiac Failure continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues, despite adequate digitalization and diuretic, Lopressor therapy should be withdrawn.

Ischemic Heart Disease: Following abrupt cessation of therapy with certain beta-blocking agents, exacerbations of angina pectoris and, in some cases, myocardial infarction have been reported. Even in the absence of overt angina pectoris, when discontinuing therapy, Lopressor should not be withdrawn abruptly, and patients should be cautioned against interruption of therapy without the physician's advice.

Bronchospastic Diseases: **PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA BLOCKERS. Because of its relative beta$_1$ selectivity, however, Lopressor may be used with caution in patients with bronchospastic disease who do not respond to, or cannot tolerate, other antihypertensive treatment. Since beta$_1$ selectivity is not absolute, a beta$_2$-stimulating agent should be administered concomitantly and the lowest possible dose of metoprolol should be used. It may be prudent initially to administer metoprolol in smaller doses three times daily, instead of larger doses two times daily, to avoid the higher plasma levels associated with the longer dosing interval. (See Dosage and Administration.)**



Still the most significant clinical advance in beta-blocker antihypertensive therapy

Major Surgery: The necessity or desirability of withdrawal of beta-blocking therapy prior to major surgery is controversial. It should be noted, however, that the impaired ability of the heart to respond to reflex adrenergic stimuli may augment the risks of general anesthesia and surgical procedures.

Metoprolol, like other beta blockers, is a competitive inhibitor of beta-receptor agonists and its effects can be reversed by administration of such agents, e.g., dobutamine or isoproterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has also been reported with beta blockers.

Diabetes Mellitus: Beta-adrenergic blockade may mask symptoms of hypoglycemia (e.g., tachycardia) and may potentiate insulin-induced hypoglycemia. Lopressor should therefore be used with caution in diabetic patients, especially those with labile diabetes.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta blockade which might precipitate a thyroid storm.

Precautions ***Impaired Hepatic or Renal Function:*** The drug should be used with caution in patients with impaired hepatic or renal function.

Drug Interactions: Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. Patients treated with Lopressor plus a catecholamine depletor should therefore be closely observed for evidence of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.

Long-Term Animal Studies: Long-term studies in animals have been conducted to evaluate toxic effects and carcinogenic potential. In a one-year study in dogs, there was no evidence of drug-induced toxicity at or below oral doses of 105 mg/kg per day. Two-year studies in rats at three oral dosage levels of up to 800 mg/kg per day did not indicate an increase in the development of spontaneously occurring benign or malignant neoplasms of any type. The only histologic changes which appeared to be drug-related were an increased incidence of generally mild focal accumulation of foamy macrophages in pulmonary alveoli and a slight increase in biliary hyperplasia. Neither finding represents symptoms of a known disease entity in man. In a 21-month study in mice at three oral dose levels of up to 750 mg/kg per day, benign lung tumors (small adenomas) occurred more frequently in female mice receiving the highest dose than in untreated control animals. There was no increase in malignant lung tumors or total (benign plus malignant) lung tumors. The overall incidence of tumors or malignant tumors was also unaffected by metoprolol administration.

Usage in Pregnancy: Reproduction studies in animals did not reveal any evidence of impaired fertility or of teratogenic potential. There was evidence in the rat of increased postimplantation loss and decreased neonatal survival (threshold between 50 and 500 mg/kg). Distribution studies in mice confirm exposure of the fetus when metoprolol is administered to the pregnant animal. There are no well-controlled studies in pregnant women. Lopressor should be used in pregnant women only when clearly needed.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Since most drugs are excreted in human milk, nursing should not be undertaken by mothers receiving metoprolol.

Usage in Children: Safety and effectiveness in children have not been established.

Adverse Reactions Most adverse effects have been mild and transient.

Central Nervous System: Tiredness and dizziness have occurred in about 10 of 100 patients. Depression was reported in about 5 of 100 patients. Headache, nightmares, and insomnia have also been reported but drug relationship is not clear.

Cardiovascular: Shortness of breath and bradycardia have occurred in approximately 3 of 100 patients. Cold extremities; arterial insufficiency usually of the Raynaud type; palpitations and congestive heart failure have been reported. See **Contraindications, Warnings,** and **Precautions.**

Respiratory: Wheezing (bronchospasm) has been reported in less than 1 of 100 patients. See **Warnings.**

Gastrointestinal: Diarrhea has occurred in about 5 of 100 patients. Nausea, gastric pain, constipation, flatulence, and heartburn have been reported in 1 of 100 or less.

Allergic: Pruritus has occurred in less than 1 of 100 patients.

Miscellaneous: Peyronie's disease has been reported in less than 1 of 100,000 patients.

The oculomucocutaneous syndrome associated with the beta blocker practolol has not been reported with Lopressor during investigational use and foreign marketing experience.

Potential Adverse Effects: In addition, a variety of adverse effects not listed above have been reported with other beta-adrenergic blocking agents and should be considered potential adverse effects of metoprolol.

Central Nervous System: Reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Cardiovascular: Intensification of AV block (see **Contraindications**).

Hematologic: Agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

Allergic: Erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress.

Miscellaneous: Reversible alopecia.

Clinical Laboratory Test Findings: Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.

Dosage and Administration Dosage of Lopressor should be individualized. The usual initial dose is 50 mg twice daily whether used alone or added to a diuretic. The dosage may be increased at weekly (or longer) intervals until optimum blood pressure reduction is achieved. In general, the maximum effect of any given dosage level will be apparent after one week of therapy. Usual maintenance dosage is approximately 100 mg twice a day, with a range of 100 to 450 mg per day. Dosages above 450 mg per day have not been studied. While twice-daily dosing is effective and can maintain a reduction in blood pressure throughout the day, some patients, especially when lower dosages are used, will experience a modest rise in blood pressure toward the end of the 12-hour dosing interval. This can be evaluated by measuring blood pressure near the end of the dosing interval to determine whether satisfactory control is being maintained throughout the day. If control is not adequate, a larger dose, or three times daily therapy, may achieve better control. Beta$_1$ selectivity diminishes as dosage of Lopressor is increased.

This drug should be stored at controlled room temperature and protected from moisture.

How Supplied Tablets of 50 mg (capsule-shaped, scored, light red, film-coated) and 100 mg (capsule-shaped, scored, light blue, film-coated) are supplied in bottles of 100 and 1,000 and Unit Dose Packages of 100.

Store at controlled room temperature and protect from moisture.

Dispense in tight, light-resistant container (USP).

C79-22 (8/79)

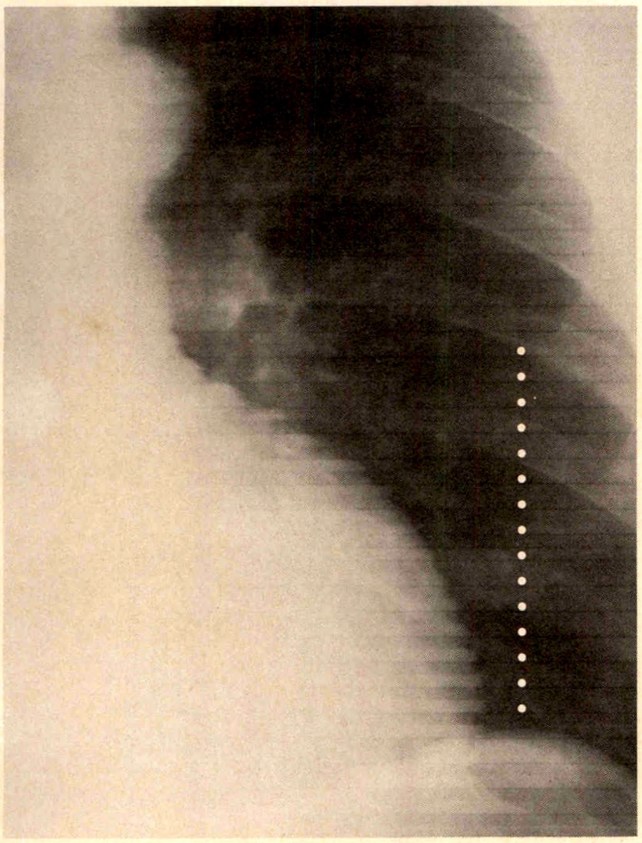
For complete details, including description, clinical pharmacology and overdosage, please see full prescribing information.

LOPRESSOR®
metoprolol tartrate

GEIGY Pharmaceuticals
Division of CIBA-GEIGY Corporation
Ardsley, New York 10502

Geigy

Now you can see coronary artery disease. In a routine X-ray.



This IRS x-ray shows an asynergistic contraction. Systolic strips are marked in this image with white dots, clearly illustrating normal motion in the basal segment, hypokinesis in the lateral wall and paradoxical motion in the apex.

Now there is a simple, accurate technique for observing and quantifying ventricular wall motion abnormalities: the InterGated™ Radiography System (IRS), from Brattle.

IRS works with existing x-ray equipment, involves no major investment, and requires no special training to use.

HOW DOES IT WORK?

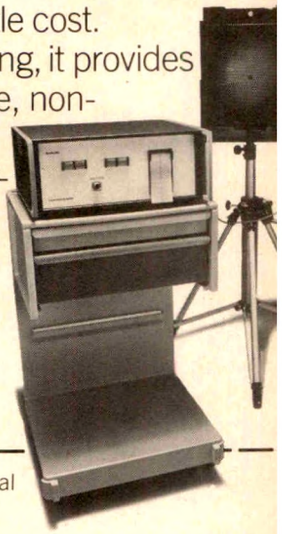
Brattle's IRS produces a serrated cardiac image showing heart motion. The IRS is able to capture the heart at end diastole and end systole during a single cardiac cycle by using ECG-gating. The result is a precise image that can be used to measure and evaluate abnormal heart wall motion, valvular defects and shunts.

Unlike Roentgenkymography, IRS is highly sensitive, highly specific and exposes the patient to no additional radiation.

WHERE IS IT USED?

Brattle's IRS is already in use in hospitals and doctors' offices, where it can dramatically increase the information content of routine x-rays at very little cost.

In addition to screening, it provides physicians with a simple, non-invasive method for monitoring patients during follow-up examination or ECG stress testing.



WANT TO LEARN MORE?

☐ Please send reprints on clinical use of Brattle's InterGated™ Radiography System.

☐ Please contact me to show me some interesting x-rays.

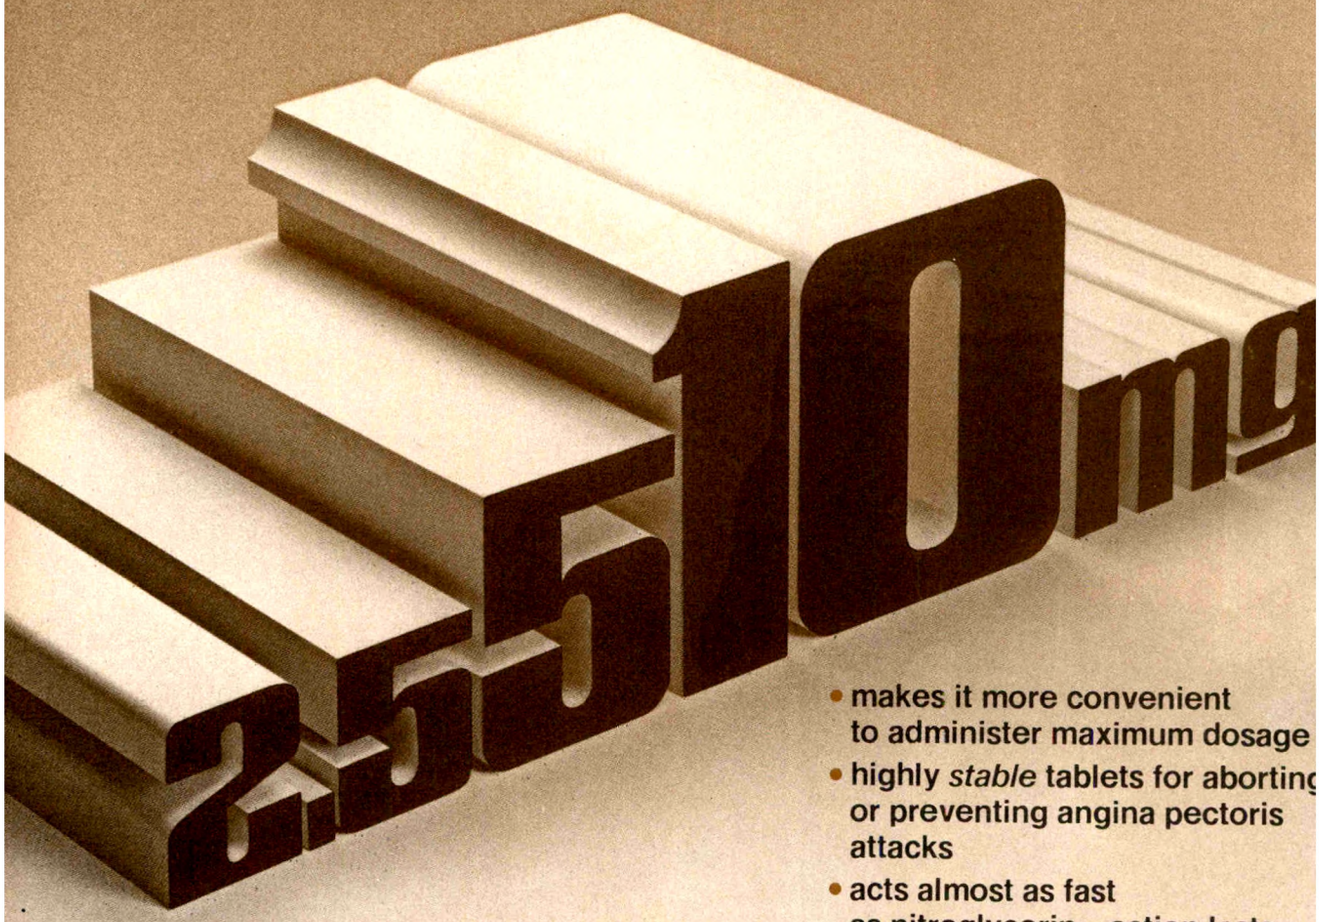
ANNOUNCING

· A "step-up" in sublingual angina* therapy



- makes it more convenient to administer maximum dosage
- highly *stable* tablets for aborting or preventing angina pectoris attacks
- acts almost as fast as nitroglycerin...action lasts up to 2 hours

now...10 mg tablet

ISORDIL® SUBLINGUAL

(ISOSORBIDE DINITRATE) SUBLINGUAL TABLETS: 2.5 mg, 5 mg, and now—10 mg

Usual dosage: one 10-mg tablet every 2-3 hours (or prn *after starting at lower dose*)

Tablets shown smaller than actual size

***Indications:** Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:
"Probably" effective: When taken by the sublingual route, Isordil Sublingual Tablets are indicated for the treatment of acute anginal attacks and for prophylaxis in situations likely to provoke such attacks. Final classification of the less-than-effective indications requires further investigation.

Contraindication: Idiosyncrasy to this drug.

Warnings: Data supporting the use of nitrites and nitrates during the early days of the acute phase of myocardial infarction (the period during which clinical and laboratory findings are unstable) are insufficient to establish safety.

Precautions: Tolerance to this drug and cross-tolerance to other nitrites and nitrates may occur.

Adverse Reactions: Cutaneous vasodilation with flushing. Headache is common and may be severe and persistent. Transient episodes of dizziness and weakness as well as other signs of cerebral ischemia associated with postural hypotension may occasionally develop. This drug can act as a physiological antagonist to norepinephrine, acetylcholine, histamine, and many other agents. An occasional individual exhibits marked sensitivity to the hypotensive effects of nitrite, and severe responses (nausea, vomiting, weakness, restlessness, pallor, perspiration and collapse) can occur even with the usual therapeutic dose. Alcohol may enhance this effect. Drug rash and/or exfoliative dermatitis may occasionally occur.

Dosage and Administration: The basic dosage for Isordil (Isosorbide Dinitrate) Sublingual Tablets is one 5-mg or 10-mg tablet every 2 to 3 hours. The 2.5-mg tablet facilitates adjustment of dosage. All three dosage strengths are used sublingually.

Consult direction circular before prescribing.

Hereditary Dysplasia of the Pulmonary Valve in Beagle Dogs

Pathologic and Genetic Studies

DONALD F. PATTERSON, DVM, DSc, FACC
MARK E. HASKINS, VMD, PhD
WILLIAM R. SCHNARR, MA*

Philadelphia, Pennsylvania

Pathologic and genetic studies were conducted in a colony of beagle dogs with pulmonary stenosis. The pulmonary valve lesions were shown in 70 affected dogs to consist of thickening, fusion and hypoplasia of valve leaflets, which occurred in varying degrees of severity and in various combinations. The gross anatomic structure of the pulmonary valve in some affected dogs resembled that seen in "typical" pulmonary stenosis in human beings; in others it was similar to what has been called pulmonary valve dysplasia. Both types, and intermediate forms, occurred in members of the same litter, indicating that these two types of pulmonary valve deformity are not separate etiologic or developmental entities in the beagle. Pulmonary valve atresia was present in two pups. Light and electron microscopic examination of affected and normal valves indicated that valve thickening, the most prominent feature of the valve abnormality, was due to an increase in the thickness of the valve spongiosa. Blood vessels and sinuses lined with endothelium were common in affected leaflets. We propose that the term *hereditary pulmonary valve dysplasia* be used to describe the entire range of pulmonary valve abnormalities in this hereditary defect of beagles.

Genetic studies, including matings of affected to affected, outcrosses, F_1 crosses and repeated backcrosses showed that pulmonary valve dysplasia is not inherited as a simple Mendelian trait. Genes at more than one locus predispose to abnormal development of the pulmonary valve. The risk of pulmonary valve dysplasia increased with inbreeding, indicating that homozygosity for specific alleles at these loci increases the probability of abnormal development. There is no evidence in affected beagles that other body systems are involved. The genetic data in beagles are consistent with available evidence concerning genetic factors involved in isolated pulmonary stenosis in human beings.

In human beings, congenital stenosis of the pulmonary valve is considered to occur in two major forms. In the "typical" form, the valve leaflets are fused but not markedly thickened, producing a dome-shaped valve with a central orifice. A less common form of valvular pulmonary stenosis, referred to as *pulmonary valve dysplasia,* is characterized by marked thickening of the pulmonary valve leaflets without fusion; obstruction to right ventricular outflow results from crowding of the valve orifice by the thickened, inflexible leaflets.[1] It is not clear whether these two forms of pulmonary valve abnormality represent variations in the expression of a common developmental disturbance or are separate entities. Nor are the underlying causes of pulmonary stenosis of either type well understood.

Epidemiologic and family studies of congenital heart disease in the dog conducted in the 1960s detected a hereditary form of pulmonary valve stenosis in beagles.[2] Affected dogs and their close relatives were subsequently obtained from owners and breeders and used to form a breeding colony in which the clinical, pathologic and genetic features of the condition could be studied in detail. The purposes of this paper

From the Comparative Cardiovascular Studies Unit, Section of Medical Genetics, and Laboratory of Pathology, School of Veterinary Medicine, University of Pennsylvania, Philadelphia, Pennsylvania. Manuscript received June 24, 1980; revised manuscript received September 2, 1980, accepted September 26, 1980.

are (1) to compare this animal model with others previously reported, (2) to examine the gross and histologic abnormalities associated with pulmonary valve lesions in this model, and (3) to investigate the mode of inheritance of pulmonary valve lesions.

Methods

Pedigree and breeding data: Beagles with pulmonary stenosis were donated for study by owners and breeders after a diagnosis of congenital heart disease was made by clinical examination at the University of Pennsylvania Small Animal Hospital. The diagnosis was confirmed by cardiac catheterization and angiocardiography. Examination of pedigrees obtained with the dogs used to form a breeding colony disclosed that some of the affected animals had common ancestors within five generations, while others did not. A series of breeding experiments was performed, consisting of the following matings: (1) affected × affected related (coefficients of inbreeding of offspring ranged from 0.125 to 0.375); (2) affected × affected unrelated (no common ancestors within five generations, coefficient of inbreeding zero); (3) affected × normal beagle with no known relation to beagles with pulmonary stenosis (this mating produced an F_1 generation of offspring); (4) normal F_1 × normal F_1 (this mating of F_1 offspring among themselves produced the F_2 generation); (5) backcross of normal F_1 female dog to an unrelated affected male dog (coefficient of inbreeding zero); (6) backcross of normal F_1 female dog to her affected sire (coefficient of inbreeding 0.25); (7) backcross of normal female dog of mating 6 to her sire-grandsire (coefficient of inbreeding 0.375).

Case material: A total of 303 pups were produced by 69 matings. Of these, 206 died or were killed before cardiac catheterization and were studied primarily by postmortem methods. The remaining 97, of which 22 were affected, were studied by cardiac catheterization and angiocardiography as well as pathologic methods. Four dogs with typical clinical signs of pulmonary stenosis are still living.

Final classification of the phenotypes of parents and offspring for the genetic analysis was made by postmortem examination of the heart, except in four dogs that are still living. These are the offspring of dogs with pulmonary stenosis and have moderate degrees of pulmonary valve stenosis with angiographic features within the range of those observed in closely related dogs examined post mortem. All affected parents used in test matings had moderate to severe pulmonary valve stenosis with thickening and varying degrees of fusion or hypoplasia of valve cusps, or both.

TABLE I

Distribution of Gross Lesions of the Pulmonary Valve Among 70 Beagles With Pulmonary Valve Dysplasia

	Dogs	
	n	%
Thickening only	18	25.7
Hypoplasia only	0	0
Fusion only	0	0
Thickening and hypoplasia	23	32.9
Thickening and fusion	15	21.4
Fusion and hypoplasia	0	0
Thickening, fusion and hypoplasia	14	20.0
Total	70	100.0

Dogs were housed in a temperature-controlled indoor colony in accordance with standard procedures used in the humane care and treatment of laboratory animals.[3] There was no known exposure to teratogenic agents. The diet consisted of Wayne dog meal with added cooked meat byproducts. Breeding was performed by artificial insemination immediately after collection of the semen. Pups were born and raised in pens with supplemental heat provided by brooder heat lamps during the first 4 weeks.

Pathologic studies: Those pups that died or were killed with barbiturate overdose underwent a complete gross autopsy examination. The hearts were examined in detail under a dissecting microscope after fixation in 10 percent buffered formalin. Histologic sections of the pulmonary valve were prepared in selected hearts and stained with hemotoxylin-eosin and in some cases with Movat's pentachrome stain. Pulmonary valves prepared for electron microscopic study were fixed immediately after death in a 2.5 percent glutaraldehyde-formalin solution, embedded in Spurr's medium[4] and stained with lead citrate-uranyl acetate. Surviving pups were anesthetized with pentobarbital sodium or halothane and studied by cardiac catheterization and angiocardiography at 8 to 12 weeks of age. Those not retained for further breeding studies were killed with a barbiturate overdose and subjected to autopsy examination.

Analysis of data: Pedigree information, together with pathologic and other data on each dog, was coded and stored on magnetic tape. Retrieval and analysis was assisted by a laboratory digital computer (Linc 8, Digital Equipment Corp., Maynard, Massachusetts).

Results

An appreciation of the spectrum of pulmonary valve anomalies observed in the offspring of matings is essential to the interpretation of clinical and genetic findings. Therefore, the results of pathologic studies will be presented first.

Pathologic Features

Of the 303 pups produced in 69 test matings, 74 (24.4 percent) had malformations of the pulmonary valve. Of these, 70 specimens were available for complete postmortem examination and form the basis of the following description of the pulmonary valve deformity.

Gross anatomy of affected valves: In general, the pulmonary valve anulus was normal or slightly reduced in size. Abnormalities of the pulmonary valve leaflets consisted of thickening, hypoplasia or fusion. These lesions occurred in various combinations and in varying degrees of severity (Table I), and all were seen in animals belonging to the same sibship.

All of the affected dogs had some degree of thickening of the pulmonary valve leaflets. The anterior, right and left leaflets were involved with about equal frequency, and in a given dog more than one of the three leaflets was usually affected. Of the 70 affected dogs, 4 had one, 24 had two and 42 had three thickened leaflets. The degree of thickening ranged from a slight increase in cross-sectional area (Fig. 1B) to bulky, nonflexible, cushion-like valve leaflets that nearly filled the valve orifice (Fig. 1D). The surfaces of the thickened leaflets, particularly the luminal surfaces and the free margins,

were often covered with small, irregular nodules (Fig. 1, C and D).

Valve leaflets were classified as hypoplastic when they were smaller than those of normal control dogs of the same age. The degree of hypoplasia varied from a slight reduction in overall size to complete absence of a leaflet (Fig. 2). Usually, only one or two of the leaflets were involved, and the reduction in size was readily apparent on comparison with others in the same valve. Affected leaflets were often misshapen as well as reduced in size. Among 37 dogs with hypoplastic leaflets, 27 had one, 5 had two and 5 had three hypoplastic leaflets. The leaflets most often involved were the left (29 dogs) and anterior (17 dogs). The right leaflet was hypoplastic in six dogs.

Pulmonary valve leaflets were considered fused when adjacent leaflets did not insert separately on the intimal surface of the pulmonary artery (fusion of commissures). The degree of fusion varied from slight (less than one fourth of the valve margins involved) (Fig. 3A) to almost complete fusion involving the entire margin and resulting in a small central orifice (Fig. 3C). The three commissures were affected with nearly equal frequency, and usually more than one commissure was

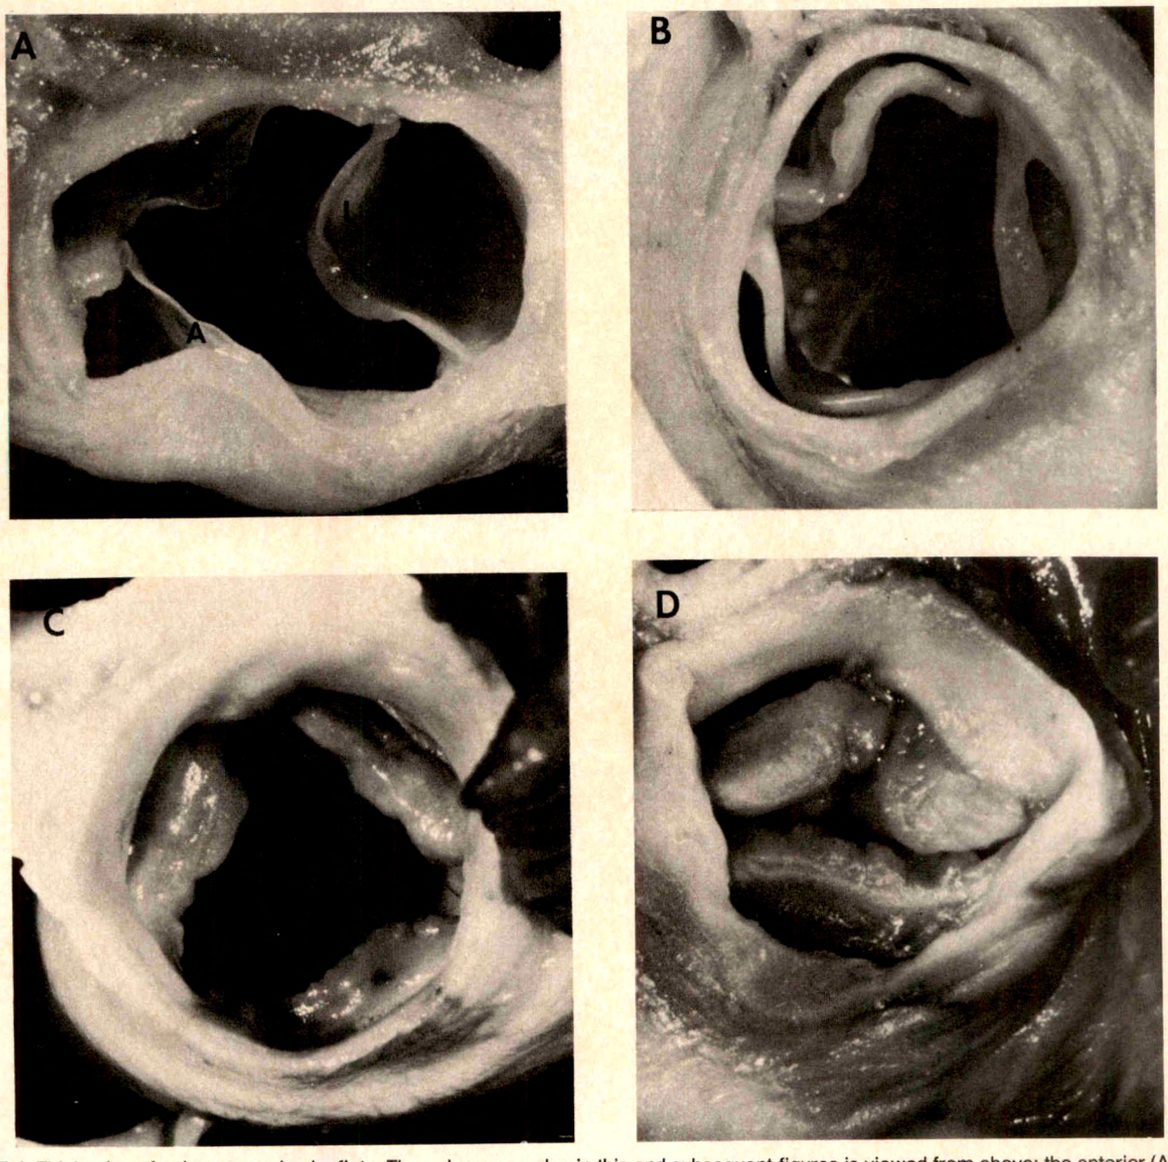

FIGURE 1. Thickening of pulmonary valve leaflets. The pulmonary valve in this and subsequent figures is viewed from above; the anterior (A) leaflet is located toward the **bottom** of the figure; the left (L) leaflet is at the **upper right** and the right (R) leaflet at **upper left. A,** pulmonary valve of a 3 month old female poodle with a normal heart. Note the thin translucent nature of the leaflets. **B**, pulmonary valve of a 3 month old female beagle with mild thickening of all leaflets. The right leaflet has irregular nodules along its free edge. **C**, moderate thickening of all three pulmonary valve leaflets in a 3 day old female beagle. The valve surface is irregular. **D**, marked thickening of all leaflets in a newborn male beagle. The leaflets consist of stiff "pads" that nearly occlude the pulmonary valve orifice.

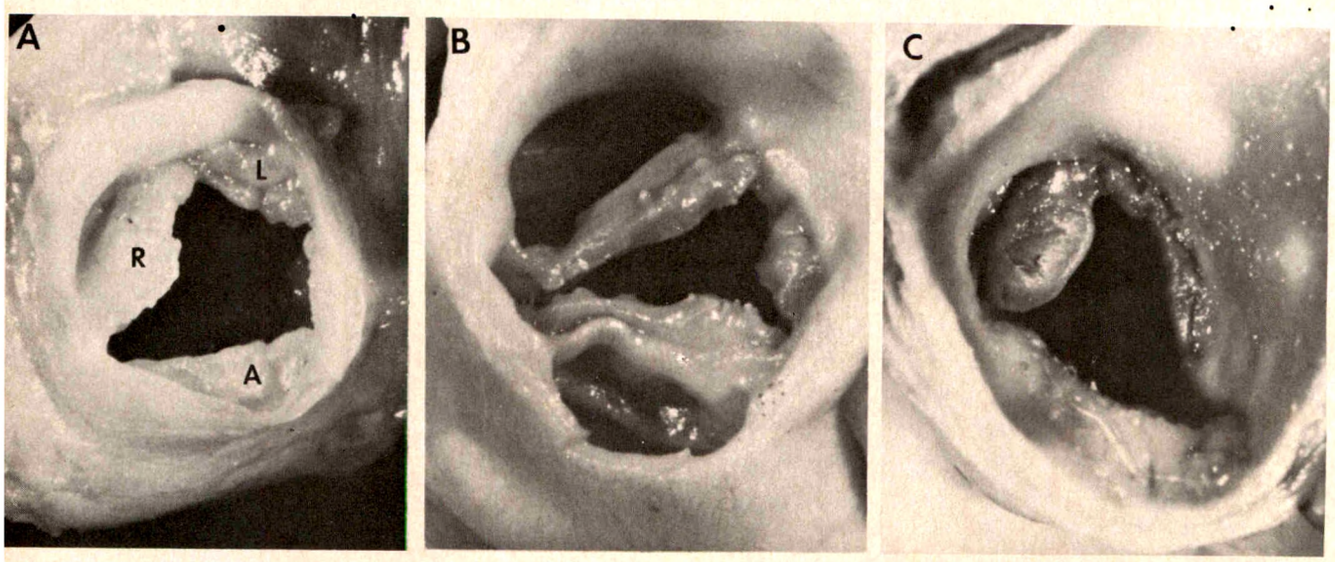

FIGURE 2. Hypoplasia of valve leaflets. **A**, thickening of all leaflets and hypoplasia of the left leaflet in a newborn male beagle. **B**, thickening and hypoplasia of the left leaflet in an 8 week old male beagle. The left leaflet is reduced to a small "pad" with no sinus of Valsalva. **C**, thickening of all leaflets and hypoplasia of the left and right leaflets in a newborn male beagle. The left leaflet is reduced to a small ridge of tissue, while the right leaflet is markedly thickened, irregular and reduced in size. The anterior leaflet consists of a thick ridge with no sinus of Valsalva. Abbreviations as in Figure 1.

involved. In some dogs, the pulmonary valve consisted of a diaphragm with a central orifice, with no evidence of separate valve leaflets (Fig. 3D). Two pups that died at 1 and 4 days, respectively, had complete atresia of the pulmonary valve, a hypoplastic valve anulus and a small cord-like main pulmonary artery. Pulmonary blood flow occurred through enlarged bronchial arteries.

Other cardiovascular malformations: Three of the 70 dogs with anomalous pulmonary valves had other cardiovascular malformations as well. One had a small subcristal ventricular septal defect and a small septum secundum atrial septal defect. The second had a small subscristal ventricular septal defect, and the third had a small patent ductus arteriosus. Cardiovascular malformations were not found in the 229 offspring that had normal pulmonary valves.

Except for the two pups with small ventricular septal defects, there were no anomalies of the crista supraventricularis as are found in Keeshond dogs with pulmonary stenosis associated with abnormal development of the conotruncal septum.[5,6] The papillary muscle of the conus was consistently present, and no aneurysms of the crista supraventricularis or evidence of the conal septum fusion line were seen (Fig. 4).

Histologic features of anomalous pulmonary valves: The histologic anatomy of the normal canine pulmonary valve is similar to that of the normal human pulmonary valve as described by Gross and Kugel.[7] In longitudinal section the valve is elongated with a wide base at the site of myocardial attachment and a slender projection into the arterial lumen (Fig. 5A). In transverse section the center of the valve cusp is narrow and is composed of three layers: the fibrosa, the valve spongiosa and the ventricularis (Fig. 5B). In dogs, as in human beings, the fibrosa is the layer located on the arterial aspect of the valve. It is covered by a layer of flat endothelial cells, may contain elastic fibrils (seen in Movat pentachrome-stained sections) and is not sharply separated from the underlying valve spongiosa. The central area, the valve spongiosa, varies in thickness and contains loose fibrillar material, fragments of collagen and widely separated cells. The ventricularis is the fibroelastic layer present on the ventricular aspect of the valve and is covered by a layer of flat endothelial cells. In transverse section of the canine valve cusp periphery, where lateral attachment to the arterial wall occurs, the valve often has projections into the sinus and is broad because of a relative increase in the dimensions of the valve spongiosa, which may have a very loose architecture. A fibroelastic connective tissue band, which is closely associated with the ventricularis in the central cusp area, crosses the valve spongiosa to become aligned along the fibrosa near the lateral attachment of the valve. Blood vessels or empty spaces lined by endothelial cells were not present in normal canine pulmonary valves.

The dysplastic valves appeared thickened in both longitudinal (Fig. 6A) and transverse (Fig. 6B) sections because of the increase in the dimensions of the valve spongiosa; many valves were as wide or wider in the central cusp area as in their periphery. Most of the thickened spongiosa consisted of loosely arranged connective tissue containing cells similar to those observed in the spongiosa of normal pulmonary valves. Also present within the spongiosa were bands of fusiform cells in a dense and regular collagen network (Fig. 6B). In transverse sections these bands were usually present in the middle of the valve and were parallel to the cusp edge. Blood-filled spaces in cross section and empty endothelial-lined spaces were present in at least one cusp of all affected animals (Fig. 6 A and B). The fibroelastic band of the ventricularis was fragmented,

reduced or absent in most cusps. The endothelial cells observed along the valve edges appeared similar in both affected and control animals.

Electron microscopy: On electron microscopy no consistent differences were observed between normal and dysplastic valves other than those described at the light microscopic level. Most cells were elongated with relatively large nuclei and prominent nucleoli (Fig. 7). The endothelial cells of the valve margin had a few microvilli projecting into the vessel lumen. The matrix consisted of short bands of collagen and granular electron-dense material loosely arranged between the cells.

Clinical Features

The primary objective of this report is to describe the pathologic and genetic features of pulmonary valve dysplasia in beagle dogs. However, the clinical features observed in the 18 affected dogs that were studied by cardiac catheterization, angiocardiography and postmortem methods will be briefly summarized for comparison with clinical features of pulmonary stenosis in human beings.

Five dogs with slightly thickened but unfused pulmonary valve leaflets had a systolic murmur in the pulmonary valve area on auscultation, but had little or no other signs of pulmonary outflow obstruction (nor-

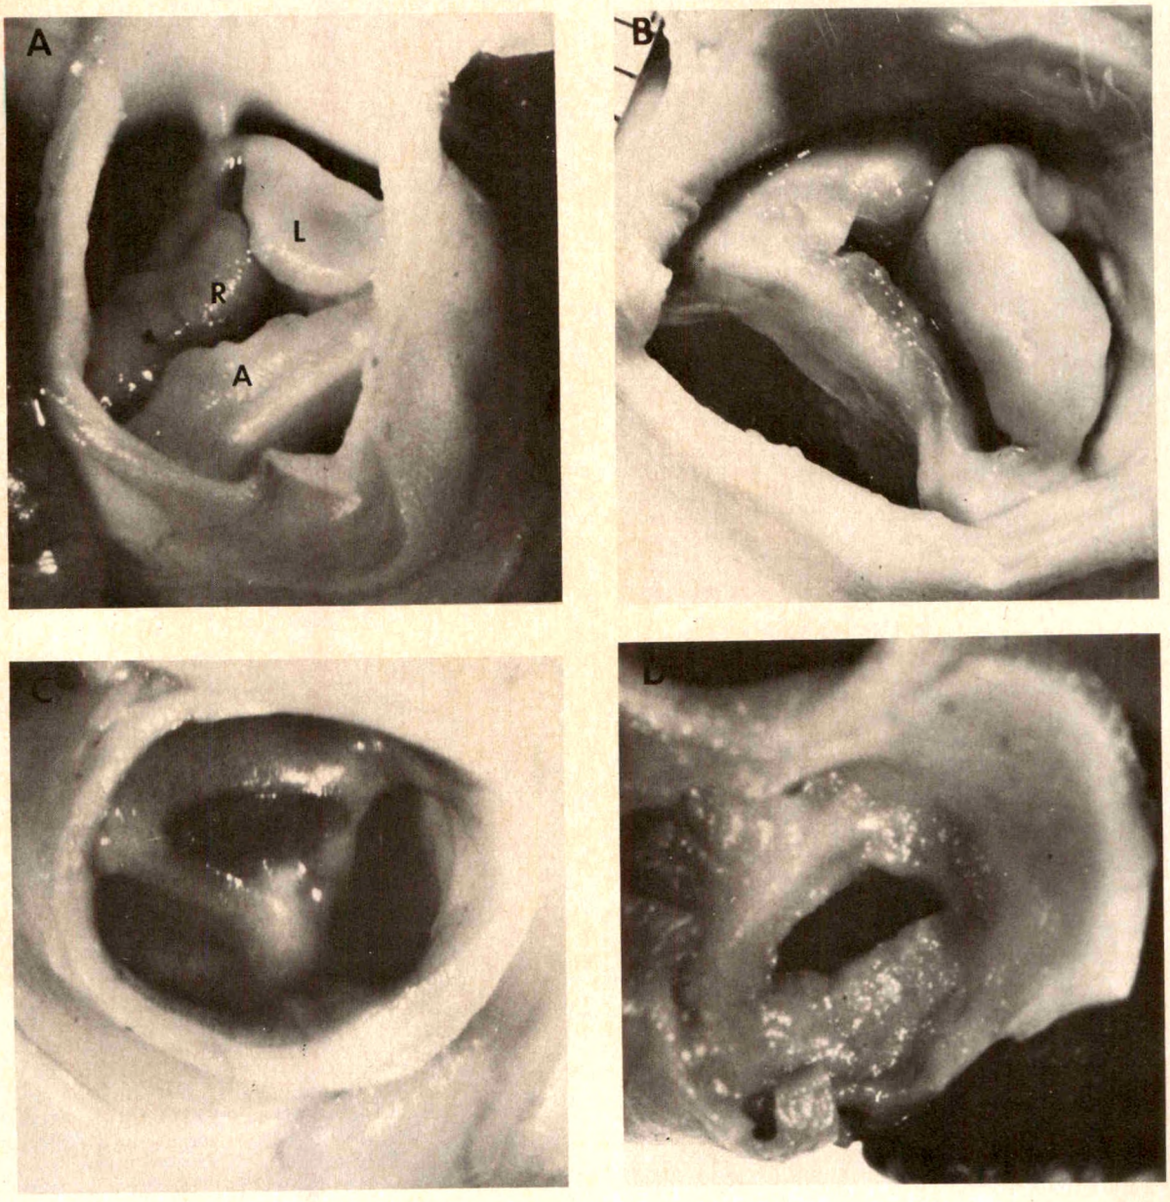

FIGURE 3. Fusion of pulmonary valve leaflets. **A**, marked thickening with minimal fusion of the right and left leaflets in a 3 day old male beagle. **B**, thickening and a more advanced degree of fusion between the anterior and right leaflets of the pulmonary valve in an 11 year old female beagle. **C**, thickening and advanced fusion of all valve leaflets in a 6 week old male beagle. **D**, the pulmonary valve in a 1 day old female beagle consists of a thick diaphragm without differentiation of leaflets. Abbreviations as in Figure 1.

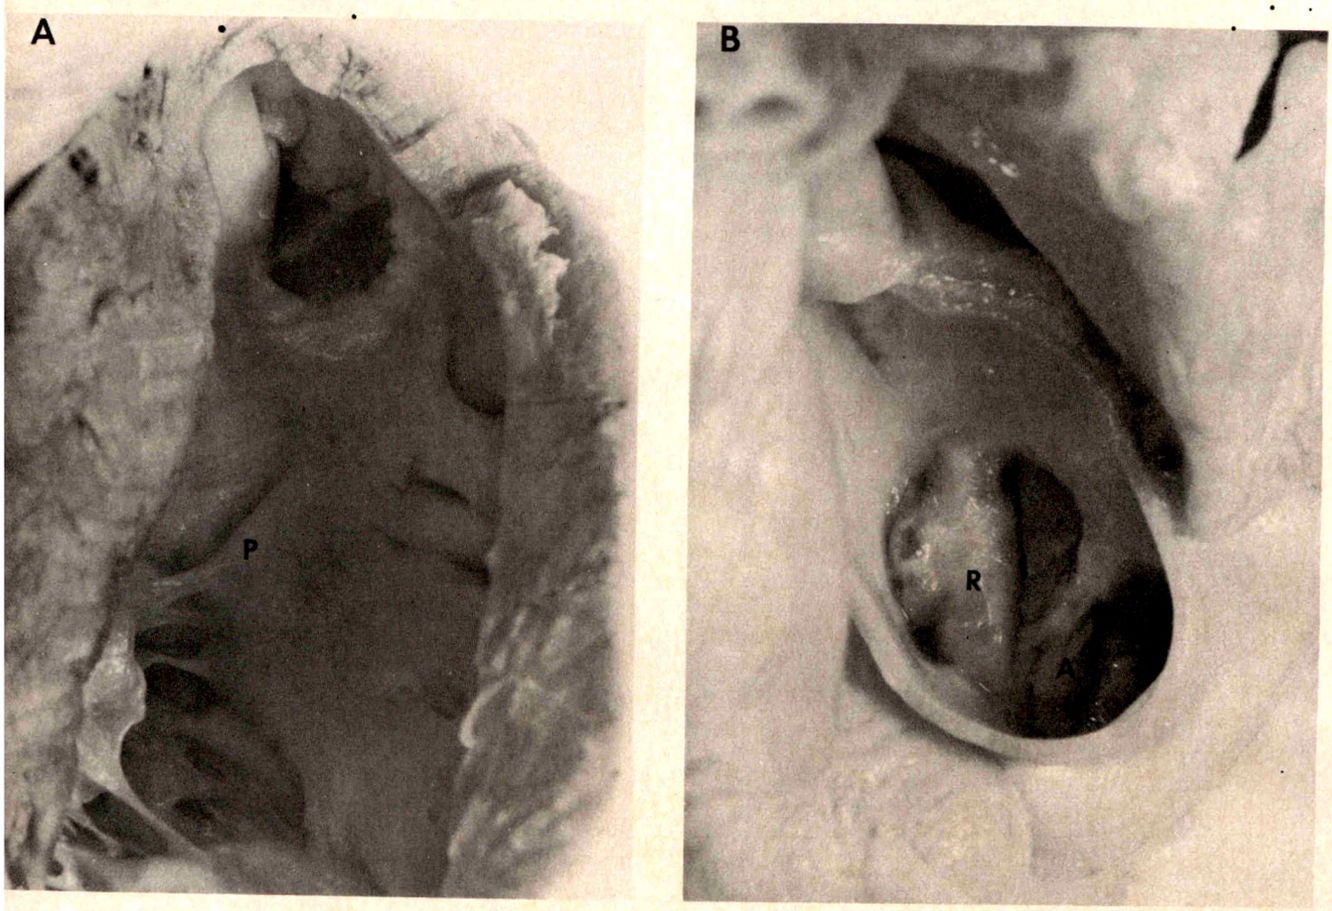

IGURE 4. Outflow tract and pulmonary valve of an 8 year old female beagle with severe pulmonary stenosis. **A**, right ventricular outflow tract showing ell developed papillary muscle of the conus (P), muscular crista supraventricularis and thickened pulmonary valve ring (**top**). B, pulmonary valve iewed from above. The right (R) and anterior (A) leaflets are thickened and fused. The anterior leaflet has a sinus of Valsalva, but the right leaflet oes not. The left leaflet is hypoplastic, resulting in a small, eccentric pulmonary valve orifice.

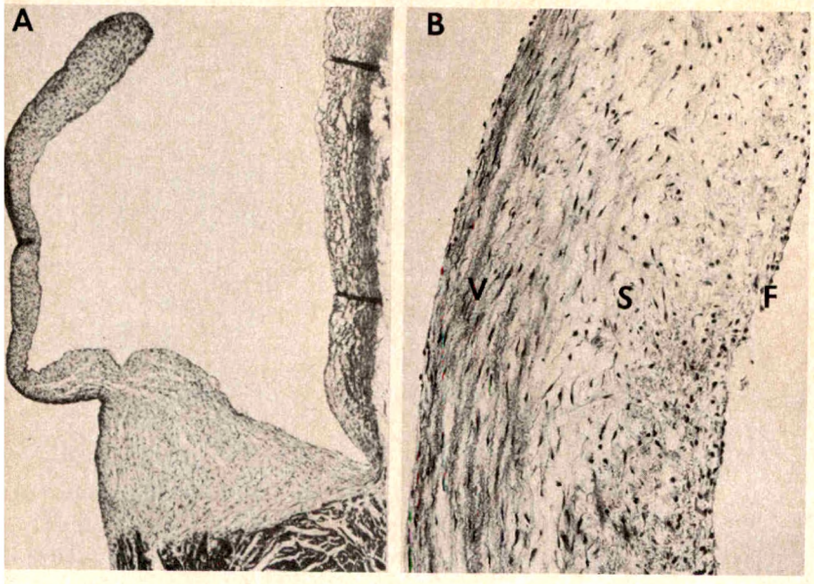

FIGURE 5. Normal pulmonary valve. **A**, light photomicrograph of a normal pulmonary valve cusp in longitudinal section. The valve has a wide base of attachment to the myocardium and a slender elongate projection into the arterial lumen. **B**, light photomicrograph of a normal pulmonary valve cusp in transverse section. The valve is composed of three layers: the fibrosa (F), the spongiosa (S) and the ventricularis (V). (Hematoxylin-eosin ×70 (**A**) and ×200 (**B**), reduced by 33 percent.)

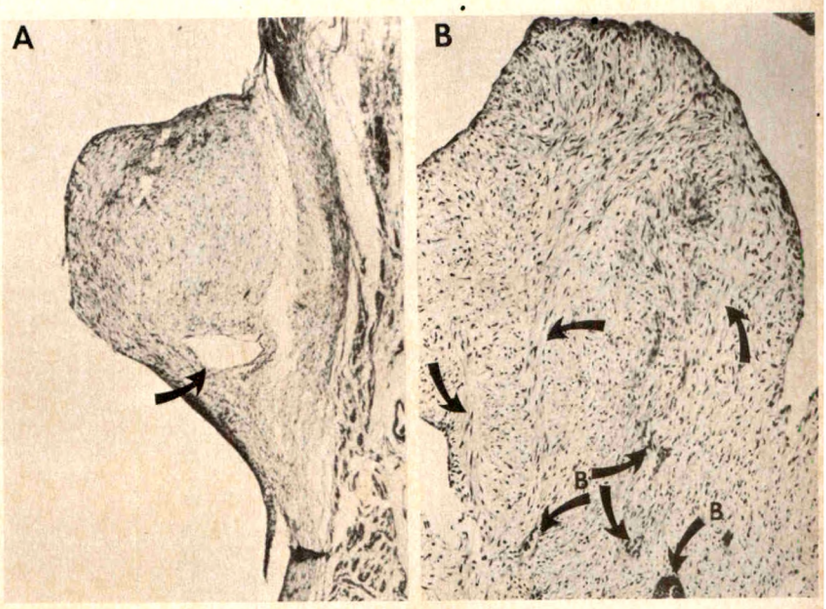

FIGURE 6. Dysplastic pulmonary valve. **A**, light photomicrograph of a dysplastic pulmonary valve in longitudinal section. The valve is short and thick and contains a large space lined by endothelial cells (**arrow**). **B**, light photomicrograph of a dysplastic pulmonary valve in transverse section. The valve is wide and contains bands of fusiform cells and collagen (**arrows**) as well as blood-filled spaces (B). (Hematoxylin-eosin ×96 (**A**) and ×145 (**B**), reduced by 32 percent.)

mal electrocardiograms and chest roentgenograms). Eleven dogs with moderate to severe thickening or fusion of leaflets, or both, had electrocardiographic signs of right ventricular hypertrophy, a loud ejection-type systolic murmur in the pulmonary valve area, radiographic evidence of right ventricular enlargement and poststenotic dilatation of the pulmonary artery. Two other dogs with a thick, diaphragm-like pulmonary valve had these signs but also had a decrescendo diastolic murmur over the pulmonary valve area and right ventricle, indicating the presence of pulmonary valve insufficiency as well as stenosis.

On cardiac catheterization, the dogs with the mildest degrees of pulmonary valve abnormality had normal right ventricular pressure and lacked a significant systolic pressure gradient across the pulmonary valve, even though grade 1/6 to 2/6 systolic ejection-type murmurs characteristic of pulmonary stenosis were present. In more severely affected animals there was clear evidence of obstruction at the level of the pulmonary valve, with right ventricular systolic pressure as high as 152 mm Hg in one animal that died at age 3 years with congestive heart failure.

Angiocardiographic abnormalities were absent in dogs with only slight degrees of valve thickening. Angiocardiograms in dogs with mild forms of dysplasia in some cases revealed thickening of pulmonary valve leaflets (Fig. 8A) or malformed sinuses of Valsalva (Fig. 8B), or both, without doming of the pulmonary valve or a central jet. Moderately to severely affected dogs had a variety of angiocardiographic abnormalities. Poststenotic dilatation of the major pulmonary artery was consistently present. When leaflets were fused but not markedly thickened, the appearance resembled that in "typical" pulmonary valve stenosis in man, with a well defined central jet and doming of the pulmonary valve during systole (Fig. 8C). Dogs with very thickened and fused valves had a thick radiolucent diaphragm that moved very little during the cardiac cycle, with a central systolic jet (Fig. 8D). Thus, clinically as well as pathologically, the spectrum of abnormalities varied from that characteristic of the "typical" form of pulmonary valvular stenosis in man to that described in recent years as pulmonary valve dysplasia.[1,8–11]

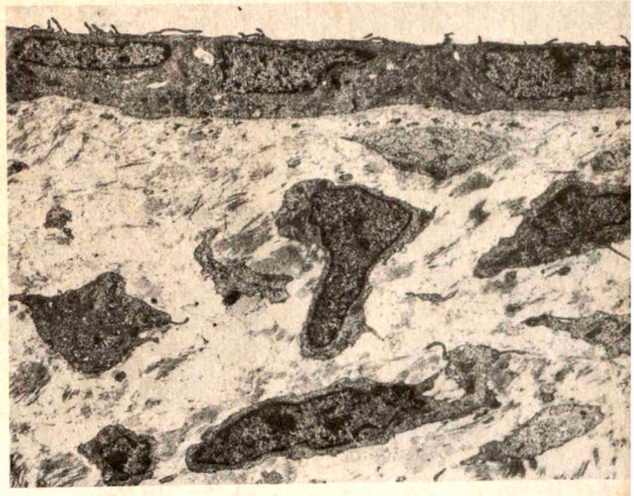

FIGURE 7. Normal pulmonary valve. Electron photomicrograph of the margin of a normal pulmonary valve. The endothelial cells have several microvilli; the inner cells contain large nuclei with relatively little cytoplasm. The matrix consists of collagen and electron-dense granular material loosely arranged around the cells. (Lead citrate-uranyl acetate ×4,750, reduced by 33 percent.)

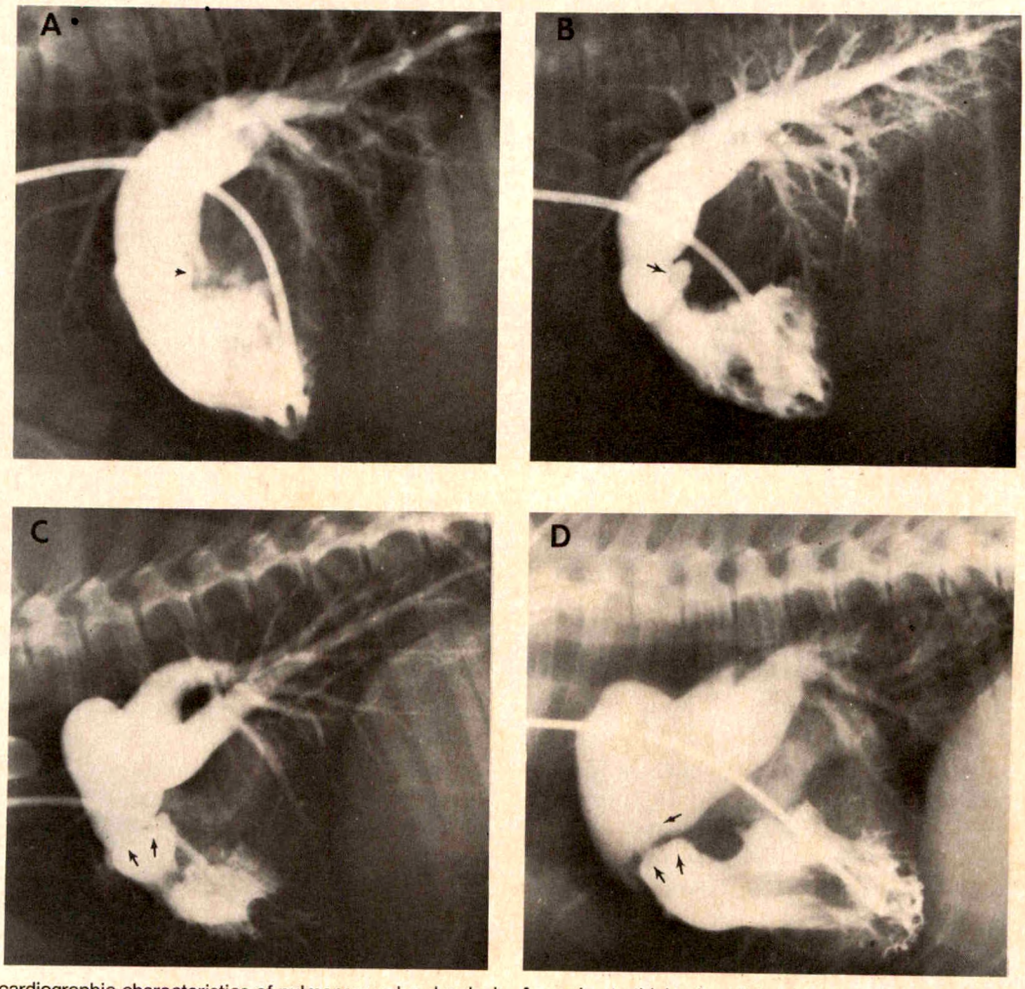

IGURE 8. Angiocardiographic characteristics of pulmonary valve dysplasia. **A**, moderate thickening of the right and anterior leaflets of the pulmonary alve in a 12 week old male beagle. The thickened right leaflet can be seen as a filling defect which changes little in appearance from one phase f the cardiac cycle to another (**arrow**). There was no significant pressure gradient across the pulmonary valve. **B**, 10 week old female beagle with ypoplasia of the left pulmonary valve leaflet and distortion of the sinus of Valsalva (**arrow**). There was no significant pressure gradient across ıe pulmonary valve. **C**, 1 year old male beagle with moderate pulmonary valve stenosis due to mild thickening and fusion of valve leaflets. Doming f the pulmonary valve during ventricular systole is clearly visible (**arrows**). Right ventricular pressure was 78/0 and pulmonary arterial pressure 8/6 mm Hg. The dog survived to age 11 years as a breeding animal. **D**, pulmonary stenosis and insufficiency in an 8 year old female beagle with ıarked thickening and fusion of valve leaflets. The thickened, "diaphragm-like" pulmonary valve (**lower arrows**) moves little from one phase of ıe cardiac cycle to another. A systolic jet is evident (**upper arrow**). Right ventricular pressure was 92/0 mm Hg.

enetic Analysis

Grading of pulmonary valve dysplasia: It is aparent from the results of our pathologic and clinical udies that the underlying developmental abnormality ads to a wide spectrum of pulmonary valve anomalies ut usually does not affect other portions of the heart. or purposes of genetic analysis, the entire spectrum ill be regarded collectively as pulmonary valve dysasia, with the degree of dysplasia classified into two ades: *Grade 1* indicates slight thickening of pulmoıry valve leaflets with little or no fusion or hypoplasia, oducing minimal or no demonstrable pulmonary ıtflow obstruction. *Grade 2* indicates moderate to vere thickening of pulmonary valve leaflets, usually th fusion or hypoplasia, or both, producing moderate severe pulmonary outflow obstruction.

Among the 303 offspring of 69 test matings, there were 74 affected pups, 19 of which had grade 1 and 55 grade 2 dysplasia. The incidence of the defect was similar in male (39 of 157 or 24.8 percent) and female animals (35 of 146 or 24.0 percent).

Results of test matings (Table II): The proportion of affected pups was highest when two dysplastic dogs were mated, but was greater when the parents were related as parent-offspring or uncle-niece (58.8 percent) than when they were unrelated* (27.6 percent) (chi-square = 4.391, df = 1, $p < 0.05$). Eight outcrosses of dogs with pulmonary valve dysplasia to normal unre-

* Although it is recognized that the dogs may have have been distantly related, there were no common ancestors within at least five generations as determined from the pedigrees available.

Normal F_1 BC female × dysplastic sire-grandsire (Fx = 0.375)	10	29	15	51.7	4	13.8	10†	34.5	14	48.3‡
All matings	69	303	229	75.6	19	6.3	55	18.1	74	24.4

* Reciprocal crosses pooled. All parents with dysplasia of the pulmonary valve had grade 2 dysplasia. † Includes two pups with pulmonary valve atresia. ‡ Within these mating types, the offspring of two related dogs had pulmonary valve dysplasia more often than those of unrelated dogs ($p < 0.05$).

BC = backcross; Fx = coefficient of inbreeding of offspring; grade 1 dysplasia = slight thickening of pulmonary valve leaflets with little or no fusion or hypoplasia, producing minimal or no pulmonary outflow obstruction; grade 2 dysplasia = moderate to severe thickening of the pulmonary valve leaflets, usually with fusion or hypoplasia or both, producing moderate to severe pulmonary outflow obstruction; unrelated = no common ancestors within five generations.

lated beagles produced 50 pups, none of which was affected. These F_1 offspring were mated among themselves to produce 42 pups in the F_2 generation, 3 (7.1 percent) of which had dysplastic pulmonary valves.

Backcrosses of phenotypically normal offspring of beagles with valve dysplastic beagles to beagles with valve dysplasia were of three types: crosses to beagles with dysplasia that were unrelated, crosses to a parent with dysplasia and second backcrosses. In the latter case, a normal female offspring of the first backcross was mated to the male that was her sire-grandsire (Table II). Although the parental phenotypes in these three types of backcrosses were equivalent (normal × affected), the proportion of affected offspring varied, being lowest when the parents were unrelated (19.1 percent) and highest when the genes of an affected sire were concentrated by two successive backcrosses (48.3 percent) (chi-square = 6.795, df = 2, $p < 0.05$).

These findings allow the following conclusions:

1. Outcrosses of affected dogs to normal unrelated beagles failed to produce any affected offspring, indicating that the gene or genes involved do not produce pulmonary valve dysplasia when present in heterozygous state. In this sense the defect can be considered "recessive."

2. It is clear that a single recessive gene with full penetrance is not an adequate explanation, because in matings of affected to affected beagles only 28 to 58 percent of the offspring were affected.

3. The risk of pulmonary valve dysplasia in backcross matings increased with the degree of inbreeding, indicating that homozygosity for alleles identical by descent increases the risk of pulmonary valve dysplasia.

4. Matings of affected to affected produced a higher proportion of affected pups when the parents were related than when they were not, again indicating that increased risk is conferred by increased homozygosity. However, in this case, it can be further inferred that two affected dogs, when unrelated, may be homozygous at different loci affecting the development of pulmonary valve dysplasia. If this were not true, no inbreeding effect would be observed.

Discussion

Pulmonary valve stenosis in human beings compared with the beagle dog: In the "typical" form of pulmonary valve stenosis in man, the valve usually has three fused commissures and a restricted central orifice, the size depending on the degree of fusion. A central jet representing rapid flow through the orifice and "doming" of the valve in ventricular systole are often seen in angiocardiograms.[11] In a rare form of pulmonary stenosis in human beings, usually referred to as pulmonary valve dysplasia, the three valve leaflets are markedly thickened and there is no commissural fusion, the obstruction resulting from crowding of the valve orifice by the redundant valve tissue; the anulus of the pulmonary valve is usually normal or slightly hypoplastic.[1,8–10] In angiocardiograms, doming of the valve is not seen and the thickened leaflets appear as filling defects in the sinuses of Valsalva.[8,11]

The etiologic and developmental relations between typical pulmonary stenosis and pulmonary valve dysplasia in human beings are unknown. Although it might be assumed that they are separate entities, this is clearly not so in the beagle dog. Our pathologic studies indicate that the same underlying genetic and developmental abnormality produces a spectrum of varying degrees of thickening, fusion and hypoplasia of valve leaflets. Some combinations result in a valve anomaly that closely resembles typical pulmonary stenosis in human beings; othere are characteristic of what has been called pulmonary valve dysplasia.[1] Indeed, both

orms and others intermediate between them were observed within a single litter. A common etiologic and developmental mechanism may underlie the different anatomic forms of pulmonary stenosis in man as well as dog. Koretzky et al.[1] reported a series of 16 patients with pulmonary valve dysplasia. Four of these patients had one or more close relatives with pulmonary stenosis, and in each family the other affected persons had the typical form.

Pulmonary valve dysplasia in the beagle: We prefer to group the entire spectrum of valve abnormalities in the beagle under the term *pulmonary valve dysplasia* because it serves to imply a spectrum of abnormal development produced by a common mechanism. Dysplastic pulmonary valve leaflets in the beagle are characterized primarily by an increase in the thickness of the spongiosa and fragmentation of the fibroelastic band of the ventricularis. Based on our observations at the light and electron microscopic levels, the cellular, fibrillar and matrix elements of the spongiosa of dysplastic valves do not appear to differ qualitatively from those of the normal valve. These findings suggest a coordinated overproduction of normal elements or a failure of the normal processes involved in conversion of the cushion-like embryonic valve primordia to the delicate leaflets present in the differentiated valve. The presence of blood vessels and sinuses in the thickened leaflets, a feature also noted in pulmonary valve dysplasia of human beings,[1] may be a primary abnormality or could be a secondary effect consequent to the increased circulatory requirement of greater valve tissue mass.

The precise nature of the underlying developmental disturbance in pulmonary valve dysplasia of beagles is not yet known, but it appears to be confined to the pulmonary valve anlagen, in contrast to the pulmonary valve anomalies found in Keeshond dogs.[5] The range of pulmonary valve malformations is similar to that in beagles, but in the Keeshond dog they are always accompanied by ventricular septal defects or minor malformations of the crista supraventricularis. The common basis for the spectrum of defects in the Keeshond dog has been shown to be a hereditary defect producing varying degrees of hypoplasia of the conotruncal septum.[6]

Genetic factors in human pulmonary stenosis: Pulmonary stenosis in human beings usually occurs as an isolated defect, but in recent years it has also been recognized as one of the features of a few rare genetic syndromes. In early studies that did not distinguish the isolated from the syndromal types, Lamy et al.[12] found the incidence of pulmonary stenosis in siblings of affected children to be 3.75 percent. This is about 100 times the incidence rate of pulmonary stenosis in children born in the general population, suggesting that genetic factors are of etiologic importance. There was an increased incidence of consanguineous marriages in the parents of affected children, indicating that homozygosity for a certain gene or genes that behave as recessives may predispose to the defect. Campbell,[13] in a somewhat later study, found a recurrence rate in siblings of 2.2 percent, whereas Sanchez-Cascos[14] removed the nonsyndromal cases from his series and found a rate of 1.5 percent. Combining reported data and their own cases, Nora and Nora[15] recently estimated the recurrence risk of isolated pulmonary stenosis in siblings as 2.0 percent and that for the offspring of patients as 3.5 percent.

Overall, evidence for the importance of genetic factors in causing isolated pulmonary stenosis in man is substantial, but it is evident that the condition is not inherited as a simple Mendelian trait. The risk of recurrence in the offspring and siblings of affected children is too low to be consistent with simple dominant inheritance. Although the increased frequency of consanguineous marriages in parents suggests recessive inheritance, the similar incidence of the defect in siblings and offspring of patients is not consistent with a simple recessive mode of transmission. Nora and Nora[15] and Sanchez-Cascos[14] pointed out that isolated pulmonary stenosis, like some other forms of congenital heart disease in man, is probably inherited as a multifactorial trait. According to this concept, genes at a number of loci (a polygenic system) as well as environmental factors influence the susceptibility to abnormal development, producing discrete malformations when some critical developmental threshold is crossed. Edwards[16] pointed out that the risk of recurrence of a polygenic trait of high heritability in the first degree relatives (parents, offspring and siblings) of affected persons should approximate the square root of the incidence of the defect in the population. This does appear to be true in some common forms of congenital heart disease, including pulmonary stenosis.[14,15]

In human beings, the atypical form of pulmonary valve stenosis referred to as pulmonary valve dysplasia occurs as one of the variable features of the Noonan syndrome, an inherited constellation of defects which also includes facial dysmorphia, small stature and mental retardation.[10,17,18] Although the affected beagle dogs in our studies often had valve anomalies that resemble those in children with the Noonan syndrome, the dogs had no apparent abnormalities of other body systems.

Implications: The results of our experimental matings of beagle dogs with pulmonary stenosis are consistent with the available evidence regarding the inheritance of isolated pulmonary stenosis in man. In both species more than one locus is involved and the risk of affected offspring is increased by inbreeding, indicating that the genes that condition abnormal development have a greater effect when in a homozygous state. In beagles it is apparent that all affected dogs are not homozygous at the same loci, since affected × affected matings produced a significantly higher proportion of affected pups when the parents were closely related than when they were not.

Management of Symptomatic Infants With Anomalous Origin Of the Left Coronary Artery From the Pulmonary Artery

DAVID J. DRISCOLL, MD, FACC*

DENTON A. COOLEY, MD, FACC
DAN G. McNAMARA, MD, FACC

Houston, Texas

There is disagreement concerning the optimal management of infants with congestive heart failure due to anomalous origin of the left coronary artery from the pulmonary artery. This report describes treatment in 23 such patients who had congestive heart failure before age 6 months. Eight patients had an operation in the 1st year of life and only two (25 percent) of these patients survived. Fifteen patients received initial medical treatment, and operation was delayed until an average age of 7.5 years; 13 (87 percent) of these patients survived. The two patients who survived early operation are still alive at an average age of 2.5 years. The 13 survivors in the medical group are still alive at an average age of 14.5 years. The age at onset and the severity of congestive heart failure were similar in the two groups. The frequency of the electrocardiographic pattern of myocardial infarction was similar in both groups. The radiographic cardiothoracic ratio was 0.74 in the surgical and 0.66 in the medical group. In 10 patients the left ventricular ejection fraction was less than 20 percent in the 1st year of life. In 7 of these 10 patients operation was performed before age 1 year and 2 (28 percent) survived; of the 3 patients treated medically, 1 (33 percent) survived.

The outcome of surgical or medical treatment of the infant with anomalous origin of the left coronary artery from the pulmonary artery may be biased by patient selection. In the infants with depressed left ventricular function, the results of surgical and medical treatment are equally disappointing. Because coronary arterial surgery in the 1st year of life in infants with severely depressed myocardial function has an extremely high mortality rate (75 percent) and because many symptomatic infants with anomalous origin of the left coronary artery from the pulmonary artery can be treated medically and survive, we recommend delay of operative intervention until at least age 18 months.

Anomalous origin of the left coronary artery from the pulmonary artery occurs in 1 of 300,000 children and constitutes approximately 0.24 percent of all congenital cardiac anomalies.[1] Despite its rarity, anomalous origin of the left coronary artery from the pulmonary artery is an important form of congenital heart disease since the mortality from this lesion has been estimated to be as high as 93 percent in the 1st year of life.[2] Also, in light of recent advances in cardiovascular operative techniques,[3,4] many investigators[5–11] recommend surgical correction of the lesion early in infancy. However, other investigators[12–14] recommend initial medical management of symptomatic infants with anomalous origin of the left coronary artery from the pulmonary artery and delay of surgical intervention until an older age. Disagreement concerning the optimal management of infants with this lesion exists, in part, for two reasons: (1) Many reported series are small with unequal distribution of patients in surgical and medical treatment groups; and (2) there is considerable variation from study to study in the criteria for assigning patients to surgical or medical treatment. At the Texas Children's Hospital we have managed a relatively large number of symptomatic

infants with anomalous origin of the left coronary artery from the pulmonary artery both surgically and medically. The purpose of this study is to review the results of the surgical and medical therapy and attempt to define the optimal management plan for these infants.

Methods

Patients: Between 1955 and March 1980 we evaluated and treated 30 patients with anomalous origin of the left coronary artery from the pulmonary artery. Two of these 30 patients had an associated ventricular septal defect and will not be discussed further.[15] In five other patients symptoms did not develop in infancy, and they will not be discussed further. The remaining 23 patients in whom symptoms of congestive heart failure developed during the first 6 months of life are the subjects of this study.

Diagnosis: All patients had diagnostic cardiac catheterization. All physiologic pressures were measured with use of fluid-filled catheters with zero pressure reference adjusted to the mid chest level. Left ventricular ejection fraction was determined from the anteroposterior left ventricular angiogram using the method of Sandler and Dodge.[16] The quality of the left ventricular cineangiogram was technically adequate to determine ejection fraction in 15 of 23 patients. The presence of a left to right shunt was determined by the appearance of contrast medium in the pulmonary artery after injection into the left ventricle or aorta. The ratio of systemic to pulmonary blood flow was calculated by the Fick method.

Fourteen patients had an M mode echocardiogram. All echocardiography was performed with a Hoffrel model 101 ultrasonascope interfaced to a Honeywell 1856 strip chart recorder. Transducers of 2.25 and 3.5 megahertz were used.

Surgery: All operations were performed using cardiopulmonary bypass and moderate systemic hypothermia (30° C). Starting in April 1977, high potassium cold cardioplegic solution was infused into the aortic root for myocardial preservation. For the purposes of this study "surgical treatment" or "surgical group" is defined as operative intervention before age 1 year and "medical treatment" or "medical group" is defined as no operative intervention or delay of operative intervention until after age 1 year.

Results

All 23 patients in whom symptoms of congestive heart failure developed before age 6 months were treated with appropriate doses of a digitalis preparation and in most cases a diuretic drug.

Surgical Group

Of these 23 patients, 8 had a cardiac operation at less than 1 year of age (Table I). The age at operation ranged from 2 to 9 months (average 4.4). All but two operations were performed using high potassium cold cardioplegic solution. Six of these eight patients had direct implantation of the ostium of the left coronary artery into the aorta, one had a saphenous vein bypass graft from the aorta to the left coronary artery and one had only ligation of the left coronary artery at its origin. Only two of these eight patients survived the operation. One of the two survivors had the benefit of high potassium cold cardioplegia and the other did not.

Each of these eight patients had cardiomegaly demonstrated by an anteroposterior chest roentgenogram. The cardiothoracic ratio ranged from 68 to 84 percent (average 74).

In seven of the eight patients an electrocardiogram was available for analysis. The electrocardiograms were performed at an average age of 3.7 months. Four of these seven patients had unequivocal electrocardiographic evidence of myocardial infarction and three did not. Of the two patients who survived operation, one had electrocardiographic evidence of myocardial infarction and the other did not.

All eight patients had cardiac catheterization and most had elevated left ventricular end-diastolic pressure ranging from 10 to 28 mm Hg (average 16). Peak systolic pulmonary arterial pressure ranged from 24 to 42 mm Hg (average 35). Peak systolic left ventricular pressure ranged from 70 to 100 mm Hg (average 85). The ratio of peak systolic pulmonary to left ventricular pressure

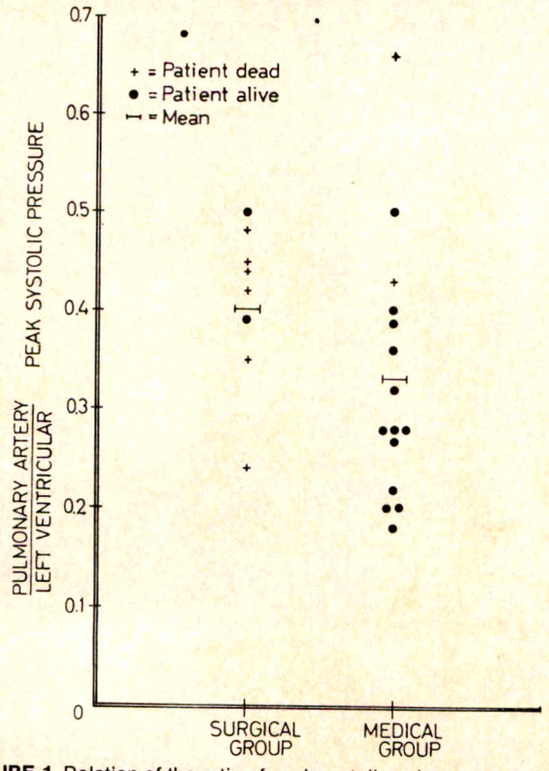

FIGURE 1. Relation of the ratio of peak systolic pulmonary arterial to left ventricular pressure to medical or surgical treatment in 23 infants.

anged from 0.24 to 0.50 (average 0.40) (Fig. 1). A reliible left ventricular ejection fraction could be determined from the left ventricular angiogram in seven of ight patients. The ejection fraction was depressed in ll and ranged from 9.2 to 24 percent (average 17). All ight patients had a dominant right coronary arterial ystem, and all had angiographic evidence of a left to ight shunt through the anomalous coronary artery. The atio of systemic to pulmonary blood flow ranged from .84 to 1.2 (average 1.05).

Seven of the eight patients had an M mode echocardiogram (Table II). The left ventricular shortening fraction was decreased in all patients, ranging from 3 to 28 percent (average 15). The ratio of left atrial to aortic root dimension ranged from 1.1 to 1.8 (average 1.5). The left ventricular end-diastolic dimension was increased in all seven patients and ranged from 3.4 to 6.5 standard deviations above the normal mean (average 4.6). All seven patients had a hypokinetic posterior ventricular wall, and two of these seven also had a hypokinetic septum.

Of the two patients who survived the operation, one has now survived 4 months and the other 4 years since operation. The cardiothoracic ratio of the latter patient has decreased from 84 percent preoperatively to 64 percent at present.

Medical Group

Operation was delayed until after 1 year of age in 15 of the 23 patients (Table III). Thirteen of these 15 patients are alive and 2 have died. The two deaths occurred at ages 16 and 17 months, respectively, and neither child had an operation. The present age of the 13 survivors ranges from 7 to 28 years (average 13.7). Of the 13 patients who survived, 9 have had an operation at an age ranging from 1.2 to 12.8 years (average 7.6). Only two of the nine operations were performed using high potassium cold cardioplegic solution. Of the nine patients who underwent operation, three had direct implantation of the left coronary ostium to the aorta, three had a saphenous vein bypass, two a left coronary arterial ligation and one a left subclavian to coronary arterial bypass. None of these patients died. Four of the 13 surviving patients have not had operative intervention; their ages range from 2 to 9 years (average 7.6).

We could determine the cardiothoracic ratio from a chest roentgenogram in 11 of these 15 medically treated patients. In the remaining four patients we either could not locate a chest roentgenogram or the quality of the roentgenogram was such that a reliable cardiothoracic ratio could not be determined. The cardiothoracic ratio for these 11 patients ranged from 52

SC = subclavian arterial to left coronary arterial anastomosis; other abbreviations as in Table I.

to 78 percent (average 66). Chest roentgenography in seven of these patients was performed in the 1st year of life (comparable with that in the surgical group), and the cardiothoracic ratio in these patients ranged from 63 to 78 percent (average 71).

Fourteen of the 15 patients had an electrocardiogram available for analysis. Electrocardiography was performed at an average age of 28.7 months. Eight of the 14 patients had unequivocal evidence of myocardial infarction, whereas 6 had no electrocardiographic evidence of infarction. Neither of the 2 patients who died had electrocardiographic evidence of myocardial infarction.

All 15 patients had cardiac catheterization at an age ranging from 2 months to 12 years. Reliable records of left ventricular end-diastolic pressure were obtained from 11 patients, and the pressure ranged from 5 to 20 mm Hg (average 10.6). Eight patients had catheterization at less than 1 year of age (comparable with the age in the surgical group), and in five of these patients left ventricular end-diastolic pressure ranged from 8 to 20 mm Hg (average 14.4). Peak systolic pulmonary arterial pressure ranged from 20 to 50 mm Hg (average 29.6). Peak systolic left ventricular pressure ranged from 75 to 120 mm Hg (average 90). The ratio of peak systolic pulmonary to left ventricular pressure ranged from 0.18 to 0.66 (average 0.33). In eight patients who had cardiac catheterization at less than 1 year of age, peak systolic pulmonary arterial pressure averaged 34.4 mm Hg, peak systolic left ventricular pressure averaged 87.5 mm Hg and the ratio averaged 0.40 (Fig. 1). A reliable left ventricular ejection fraction could be determined from the left ventricular angiogram in 8 of the 15 patients and ranged from 12 to 68 percent (average 36.5). In five of these patients catheterization was performed at less than 1 year of age (comparable with the age in the surgical group), and the ejection fraction ranged from 12 to 68 percent (average 31.8). All 15 patients had a dominant right coronary arterial system and all had angiographic evidence of a left to right shunt through the anomalous left coronary artery. The ratio of systemic to pulmonary blood flow ranged from 0.90 to 1.16 (average 1.05).

Six of the 15 patients underwent M mode echocardiography at an age ranging from 9 months to 7 years (Table IV). The left ventricular shortening fraction ranged from 6 to 33 percent (average 26.7). The ratio of the left atrial and aortic dimension ranged from 1.1 to 1.6 (average 1.4). The left ventricular end-diastolic dimension ranged from 1.4 to 4.9 standard deviations above the normal mean (average 2.7). Left ventricular hypokinesia was noted in only 1 patient, who died during medical treatment.

Infant Subset

Ten of the 23 patients had cardiac catheterization with a documented left ventricular ejection fraction of less than 20 percent in the first 11 months of life. This subset of patients tended to have more severe symptoms of congestive heart failure and a greater cardiothoracic ratio on chest roentgenography than did patients with an ejection fraction greater than 20 percent. Seven of these patients were treated surgically and 2 are alive (28 percent survival rate). The five deaths occurred in the immediate postoperative period at ages 2, 2, 4, 5 and 9 months, respectively. Of the two survivors, one has had a reduction in cardiac size with a decrease in the cardiothoracic ratio from 84 to 64 percent. The other patient is early in the follow-up period. Both patients continue to require digitalis and diuretic therapy. Three of the 10 patients were treated medically and 1 is alive (33 percent survival rate). The two deaths occurred at

16 and 14 months of age, respectively. The one survivor has had spontaneous improvement of the left ventricular ejection fraction from 15 percent at age 8 months to 33 percent at age 48 months. At age 5 years, after myocardial revascularization at age 48 1/2 months, she has a left ventricular ejection fraction of 57 percent.

Discussion

Natural history and prognosis: There is considerable disagreement concerning the optimal management of symptomatic infants with anomalous origin of the left coronary artery from the pulmonary artery. Some investigators[5–11] suggest that surgical intervention either to ligate the left coronary artery or to establish prograde flow through this artery is indicated as soon as the diagnosis is established. This aggressive surgical approach stems, in part, from the previously reported poor prognosis for patients with this anomaly. Wesselhoeft et al.[2] reported a 93 percent mortality rate for infants with this anomaly in whom symptoms developed between 2 and 4 months of age. Perry and Scott[13] reported on 11 infants with anomalous origin of the left coronary artery from the pulmonary artery in whom symptoms of congestive heart failure developed at age 3 weeks to 4 months. Only 2 of these 11 patients survived (82 percent mortality rate). Four of their patients were treated surgically and three died (75 percent mortality rate); of the seven treated medically, six died (85 percent mortality rate).

However, the frequent assumption that symptomatic infants with anomalous origin of the left coronary artery from the pulmonary artery have an invariably poor prognosis may be incorrect. Perry and Scott[13] reviewed 4 previously reported cases of anomalous origin of the left coronary artery from the pulmonary artery and found a mortality rate of only 32 percent. Arciniegas et al.[5] reported an overall mortality rate of 34 percent. A previous study from this center reported a 20 percent mortality rate in 10 patients with anomalous origin of the left coronary artery from the pulmonary artery. Indeed, the two deaths occurred after ligation of the left coronary artery. The overall mortality rate for symptomatic infants with this anomaly in the present study is 34 percent. Indeed, on the basis of our study and previous studies,[3,10,11] the overall mortality rate for symptomatic infants with anomalous origin of the left coronary artery from the pulmonary artery is between 30 and 35 percent.

How can one reconcile the disparate reports of the natural history of this cardiac malformation? As with most diseases, there is a selection process so that the sickest patients come to medical attention earlier than less severely affected patients. Also, some patients are misdiagnosed as having endocardial fibroelastosis, myocarditis or idiopathic congestive cardiomyopathy and are discovered only later in life to have anomalous origin of the left coronary artery from the pulmonary artery. In some published studies patient records are sought through hospital files as well as autopsy files. These factors tend to select the sickest patients with the disease and will bias the mortality data and the reported natural history. It is important to recognize this bias because an understanding of the natural history of the disease is critical in making any reasonable decision concerning the effect of therapy.

Subset of patients with poor prognosis during 1st year of life: In this study the patients operated on at less than 1 year of age appear to have been sicker than those treated medically. Although all patients in both the medical and the surgical groups were symptomatic, the surgical group had cardiac catheterization at an earlier age, had a higher left ventricular end-diastolic pressure, a higher peak systolic pulmonary pressure and ratio of peak systolic pulmonary to left ventricular pressure and a lower left ventricular ejection fraction than did the medical group. Thus it appears that selecting the sickest patients for operation in this study creates a bias against the operative results. However, when one examines the outcome of patients with a left ventricular ejection fraction of 20 percent of less, both medical (33 percent survival rate) and surgical (28 percent survival rate) modes of therapy have similar survival results. This finding suggests that there is a subset of patients with anomalous origin of the left coronary artery from the pulmonary artery and very poor left ventricular function who will have a very high mortality rate in the 1st year of life regardless of therapy. However, there is a large group of patients with a

left ventricular ejection fraction greater than 20 percent who will survive without early surgical intervention and who should be spared the risk of operation in the 1st year of life.

Role of left ventricular function in surgical decision: Although surgery in the 1st year of life is no better and perhaps worse than medical management in promoting survival, does early surgical myocardial revascularization decrease the progression of left ventricular fibrosis and preserve or improve myocardial function? The answer is unclear. Levitsky et al.[6] reported on a 10 month old child who had direct implantation of the left coronary artery into the aorta. Seven months postoperatively this patient had improved left ventricular function. The left ventricular ejection fraction increased from 30 to 48 percent, end-diastolic pressure decreased from 10 to 7 mm Hg, and the first derivative of left ventricular pressure (dP/dT) increased from 400 to 1,375 mm/s. One of our two survivors of early surgical intervention had a reduction of the cardiothoracic ratio on chest roentgenography from 84 percent at age 2 months to 64 percent at age 21 months. For the other survivor it is still too early in the postoperative period to be able to judge the effect. However, we have seen improvement of left ventricular function with medical therapy only. Patient M-5 had a left ventricular ejection fraction of 15 percent at age 8 months, and at age 48 months it was 33 percent without operative myocardial revascularization. Ihenacho et al.[17] also reported spontaneous improvement in a patient with anomalous origin of the left coronary artery from the pulmonary artery.

Recently Arciniegas et al.[5] reported the outcome of 23 patients with anomalous origin of the left coronary artery from the pulmonary artery treated in their institution. Six of 23 infants died between 2 and 8 months of age without surgical intervention. Seventeen patients were treated by a variety of operative techniques (ligation of the left coronary artery, 4 patients; implantation of the left coronary artery into the aorta, 1 patient; saphenous vein bypass graft, 7 patients; and subclavian to coronary arterial bypass graft, 5 patients), and 2 of these 17 patients died. These investigators concluded that reestablishment of a two coronary arterial system is the procedure of choice, especially in infancy. We must disagree with their conclusion. Both their study and the present study reviewed the course of 23 patients, and in both studies 8 patients died. However, in one study early surgical intervention is advocated, while in the other medical therapy with delayed surgical intervention is advocated. These disparate conclusions are probably a result of the difference in the selection of the medical and surgical groups in the two studies. While we tended to select the sickest patients for early surgical intervention, the Arciniegas report[5] suggests that they elected not to operate on the youngest, sickest patients. The different conclusions of those two studies highlight the possibility that there are two subsets of symptomatic infants with anomalous origin of the left coronary artery from the pulmonary artery. One subset includes very sick infants with a markedly decreased left ventricular function who have a mortality rate of approximately 70 percent regardless of the mode of therapy. The other subset will do well regardless of the mode of therapy with essentially no mortality. It is important that the patients in the latter subset not be subjected to the risk of early surgical intervention but be managed by medical means until they reach an age and size when an operation has minimal risk.

Role of magnitude of left to right shunt and pulmonary hypertension: Other investigators have suggested that the magnitude of the left to right shunt and the degree of pulmonary hypertension predict outcome and can be used as a guideline for surgical or medical therapy. Perry and Scott[13] reviewed 44 cases and classified the patients into three groups: (1) those with sufficient intercoronary anastomosis to be associated with an increase in oxygen saturation in the pulmonary artery, (2) those with intercoronary anastomosis insufficient to produce an increase in oxygen saturation in the pulmonary artery but with a left to right shunt at the level of the pulmonary artery detectable by dye dilution curves or by cineangiography, and (3) those with no detectable evidence of a left to right shunt in the pulmonary artery or pulmonary hypertension, or both. Askenazi and Nadas[14] recommend that infants with a "sizable" left to right shunt be treated conservatively until attaining an age and size suitable for coronary arterial bypass. If only a small left to right shunt is demonstrable, these investigators recommend surgical intervention because the prognosis with conservative therapy is poor.

In our study, we could demonstrate no relation between the magnitude of the left to right shunt and outcome with either early surgical or medical therapy. The ratio of systemic to pulmonary blood flow was 1.05 in both the medically and the surgically treated patients. Although the ratio of systemic to pulmonary blood flow in the patients who died (Qp/Qs ratio = 1.03) was slightly smaller than in those who survived (Qp/Qs ratio = 1.06), this difference was not statistically significant. There was a relation between the ratio of peak systolic pulmonary arterial and left ventricular pressure and outcome. The average ratio of peak systolic pulmonary arterial to left ventricular pressure was 0.43 for the patients who died and 0.32 for those who survived. Also, the ratio of peak systolic pulmonary arterial to left ventricular pressure was greater in the patients operated on (0.40) than in those treated medically (0.33). An increased ratio of peak systolic pulmonary artery to left ventricular pressure probably reflects reduced left ventricular function and associated mitral regurgitation and is an index of the severity of disease. Indeed, it supports the contention that we selected sicker patients for operative intervention than we selected for medical therapy.

Recommendation for patient management: Our present recommendations for the management of symptomatic infants with anomalous origin of the left

coronary artery from the pulmonary artery are as follows: (1) Treat patients with evidence of recent myocardial infarction according to the principles of modern coronary care. These include rest and administration of oxygen, morphine when indicated, digitalis, diuretic drugs and appropriate antiarrhythmic agents.[14] (2) Continue appropriate doses of digitalis and diuretic drugs for the patients with congestive heart failure but without recent acute myocardial infarction. Afterload-reducing agents may be beneficial in some of these patients, but this is unproved in infants. (3) Delay operative revascularization until patients are at least 18 months of age and in many cases until 5 to 7 years of age. At the time of operation attempt to establish a two coronary system rather than perform simple ligation of the left coronary artery. The risk of surgical intervention in the 1st year of life is prohibitively high.

Coronary Artery Disease in the Hurler Syndrome

Qualitative and Quantitative Analysis of the Extent of Coronary Narrowing at Necropsy in Six Children

FRANK C. BROSIUS, III, MD*
WILLIAM C. ROBERTS, MD, FACC

Bethesda, Maryland

The amount of cross-sectional area luminal narrowing in each 5 mm segment of each of the four major epicardial coronary arteries (right, left main, left anterior descending and left circumflex) is described at necropsy in six children (aged 3 to 16 years) with the Hurler syndrome. In five patients at least one of the four major coronary arteries was narrowed 76 to 100 percent, and in four of these five patients all four major arteries were narrowed to this extent. Of the 24 major coronary arteries in the six patients, 17 (71 percent) were narrowed 76 to 100 percent at some point. A total of 182 segments were examined from the 24 major coronary arteries, and the extent of narrowing was as follows: 96 to 100 percent, 14 (8 percent); 76 to 95 percent, 61 (34 percent); 51 to 75 percent, 59 (32 percent); 26 to 50 percent, 39 (21 percent) and 0 to 25 percent, 9 (5 percent). By applying a score of 1 to 4 to each 5 mm segment according to its category of narrowing (1 = 0 to 25 percent; 2 = 26 to 50 percent; 3 = 51 to 75 percent and 4 = 76 to 100 percent), the 182 segments had a total score of 570 and a mean score of 3.2, indicating that each segment was narrowed an average of about 67 percent in cross-sectional area. Thus, narrowing of the major epicardial coronary arteries at necropsy is usually diffuse and severe in the Hurler syndrome, which is the cause of the most severe coronary narrowing in childhood.

Patients with the Hurler syndrome (dwarfism, severe mental retardation skeletal malformations, hepatosplenomegaly and corneal opacities) are known to have a variety of cardiovascular lesions that affect the coronary arteries, cardiac valves, mural endocardium, myocardial walls and aorta.[1–6] Within the affected cardiac structures are large clear cells (known as Hurler cells), granular cells, acid mucopolysaccharide materia and collagen.[6] Although it is well known that the epicardial coronary arteries may be narrowed in the Hurler syndrome,[6] the extent of the narrowing has not been described. To fill this void, each of the four major epicardial coronary arteries in six patients with the Hurler syndrome was examined in a quantitative manner at necropsy, and the results of that examination are described in this report.

Methods

Study patients: During life, none of the six patients with the Hurler syndrom had symptoms of cardiac dysfunction or evidence of myocardial ischemia. Specifically, none had dyspnea, evidence of chest pain or overt signs of congestive cardiac failure. Three had precordial murmurs (grade 2/6, apical, systolic), and three had cardiomegaly on chest radiography. Electrocardiograms were available for all but one patient (Case 1): in four, they were recorded during the last 2 weeks of life, and in the remaining patient (Case 3), 8 years before death. None of the five had electrocardiographic evidence of myocardial ischemia. All five had sinus tachycardia, two patients (Cases 3 and 5) had right axis deviation and right atrial abnormality, one patient (Case 6) had low voltage and one (Case 5) had occasional premature ventricular beats. None had unequivocal evidence of either right or left ventricular hypertrophy.

At necropsy, each had diffuse thickening of all four cardiac valves and of ventricular mural endocardium, and three had calcific deposits in mitral anuli. All six also had Hurler cells in the interstitium between some myocardial cells. One patient had a small focus of subendocardial fibrosis. Atherosclerotic plaque in the aorta was impressive. These noncoronary cardiovascular findings in five of the six patients are described in detail elsewhere.[6]

Coronary arterial examination: Grossly, the right, left main, left anterior descending and left circumflex coronary arteries (hereafter called the four major coronary arteries) were firm and the amount of surrounding subepicardial adipose tissue was minimal (Fig. 1). The coronary arteries were examined as follows: Each was excised intact, fixed and cut transversely to its longitudinal axis into segments approximately 5 mm long, and each segment was labeled sequentially from either its aortic ostium or from its origin from the left main artery. The 5 mm segments were labeled, dehydrated (alcohol and xylene) and embedded in paraffin, and two histologic sections were cut and stained from each paraffin block. Movat stain was used on one histologic section, and all determinations of luminal narrowing were based on examination of the Movat-stained sections. The degrees of luminal narrowing were based on histologic examination of each cross section magnified 25 to 50 times.

The judgment regarding the degree of luminal narrowing of each 5 mm segment was based on the degree of luminal obliteration within the luminal circle bordered by the internal elastic membrane. The circle was visually subdivided into four equal-sized quadrants, and the extent of cross-sectional area luminal narrowing in each 5 mm segment was classified as follows: 0 to 25, 26 to 50, 51 to 75 or 76 to 100 percent. The latter category was subdivided into 76 to 95 and 96 to 100 percent to determine the number of segments totally occluded or nearly so. The accuracy of these judgments by visual inspection under microscopy has been shown by comparison with video planimetry to have a rate of error of less than 5 percent.[7]

Results

Of the 24 total major epicardial coronary arteries in the six patients with the Hurler syndrome, 17 (71 percent) were narrowed 76 to 100 percent in cross-sectional area at some point, an average of 2.8 coronary arteries per patient. In four patients all four major coronary arteries were narrowed 76 to 100 percent in cross-sectional area; in one patient (Case 3) only one of the four arteries and in another (Case 6) none of the four arteries was severely narrowed. In four of the six patients, the left main coronary artery was severely narrowed (76 to 100 percent).

Quantitative analysis of coronary segments: The results of the quantitative analysis of the 5 mm long coronary segments from each of the four major coronary arteries in each of the six study patients are summarized in Figure 2 and Table I, and the amounts of narrowing in each of the four major arteries in the six patients are summarized in Figure 3. Of the 182 coronary segments examined in the six patients, 14 (8 percent) were narrowed 96 to 100 percent in cross-sectional area; 61 (34 percent) 76 to 95 percent; 59 (32 percent) 51 to 75 percent; 39 (21 percent) 26 to 50 percent; and 9 (5 percent) to 25 percent. Although the overall amount of narrowing was extensive, there was considerable variation among the six patients. The most severe narrowing occurred in Patients 4 and 5, who were brothers: all 47 of their coronary segments (100 percent) were narrowed 76 to 100 percent in cross-sectional area, including 11 segments (23 percent) narrowed 96 to 100 percent. In Patient 2, 58 percent of the segments were narrowed 76 to 100 percent, and in Patient 1 (the youngest, age 3 years), 26 percent were so narrowed. In contrast, in Patient 3 only 1 (3 percent) of 37 segments was severely narrowed (76 to 100 percent), and in Patient 6 (the oldest of the six patients, age 16 years), none of the 32 segments was severely narrowed.

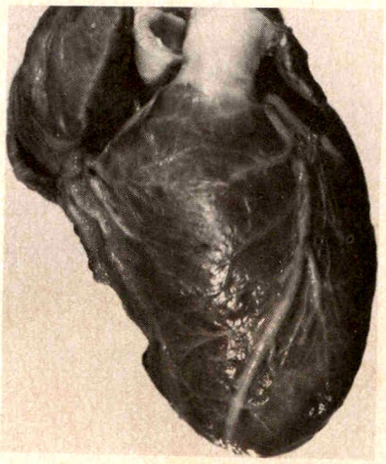

FIGURE 1. Patient 5. Epicardial surface of the heart. The left anterior descending coronary artery is far more prominent than expected for an 11 year old boy (A70-236) because of the artery's firmness (from the intraluminal deposits of Hurler cells, granular cells, collagen and acid mucopolysaccharide material), and the expected adjacent subepicardial adipose tissues are absent.

The extent of the coronary narrowing in each of the six patients and in the six patients as a whole also can be readily appreciated by applying a numerical score to the amount of cross-sectional area narrowing in each 5 mm coronary segment, as follows: narrowing 0 to 25 percent = 1; 26 to 50 percent = 2; 51 to 75 percent = 3; and 76 to 100 percent = 4 (Table I). Of the 182 segments, the total score was 570 and the mean score 3.2. Thus, each of the 5 mm segments was narrowed an average of about 67 percent in cross-sectional area, and the mean scores in the six patients ranged from 2.2 (Patient 3) to 4 (the highest possible score, found in the two brothers, Patients 4 and 5). The percent of coronary segments classified in each of the five categories of narrowing was similar in all four major coronary arteries (Fig. 3).

Histologic analysis: The coronary luminal narrowing in all six patients and in all 182 coronary segments was produced primarily by a combination of Hurler cells, granular cells, collagen and acid mucopolysaccharide material (Fig. 4). In only one patient (Case 5) were lipid deposits, namely, foam cells and a few extracellular lipid accumulations, found in the coronary arteries. Only one patient (also Patient 5) had calcific

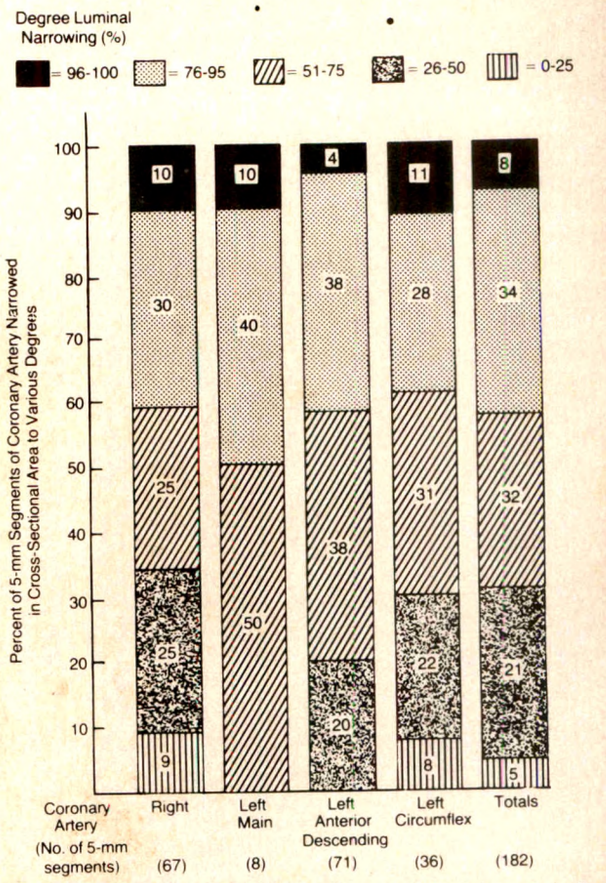

FIGURE 3. Bar graph showing the percent of 5 mm segments in five categories of narrowing in each of the four major epicardial coronary arteries in the six patients.

deposits, but these were present in only 1 of 19 segments.

Comments

Coronary artery disease in Hurler's syndrome: This necropsy study indicates that patients with the Hurler syndrome usually have diffuse and severe coronary luminal narrowing produced primarily by a combination of Hurler cells, fibrous tissue and acid mucopolysaccharide material. The presence of the Hurler cells indicates the specific cause of the luminal narrowing. The amount of coronary luminal narrowing was severe (76 to 100 percent) in five of the six patients, and in all six it was far more extensive than expected in the first 2 decades of life. Of the 24 coronary arteries studied in the six patients, 17 (71 percent) were narrowed 76 to 100 percent in cross-sectional area, and in

TABLE I

Number, Total Score and Mean Score of the 5 mm Segments of the Four Major Epicardial Coronary Arteries Narrowed to Various Degrees in Each Patient

Case	5 mm Coronary Segments With Various Degrees of Narrowing in XSA (n)				Total 5 mm Segments	Score	
	0–25%	26–50%	51–75%	76–100%		Total*	Mean†
1	3	4	19	9	35	104	3.0
2	0	3	10	18	31	108	3.5
3	6	18	12	1	37	82	2.2

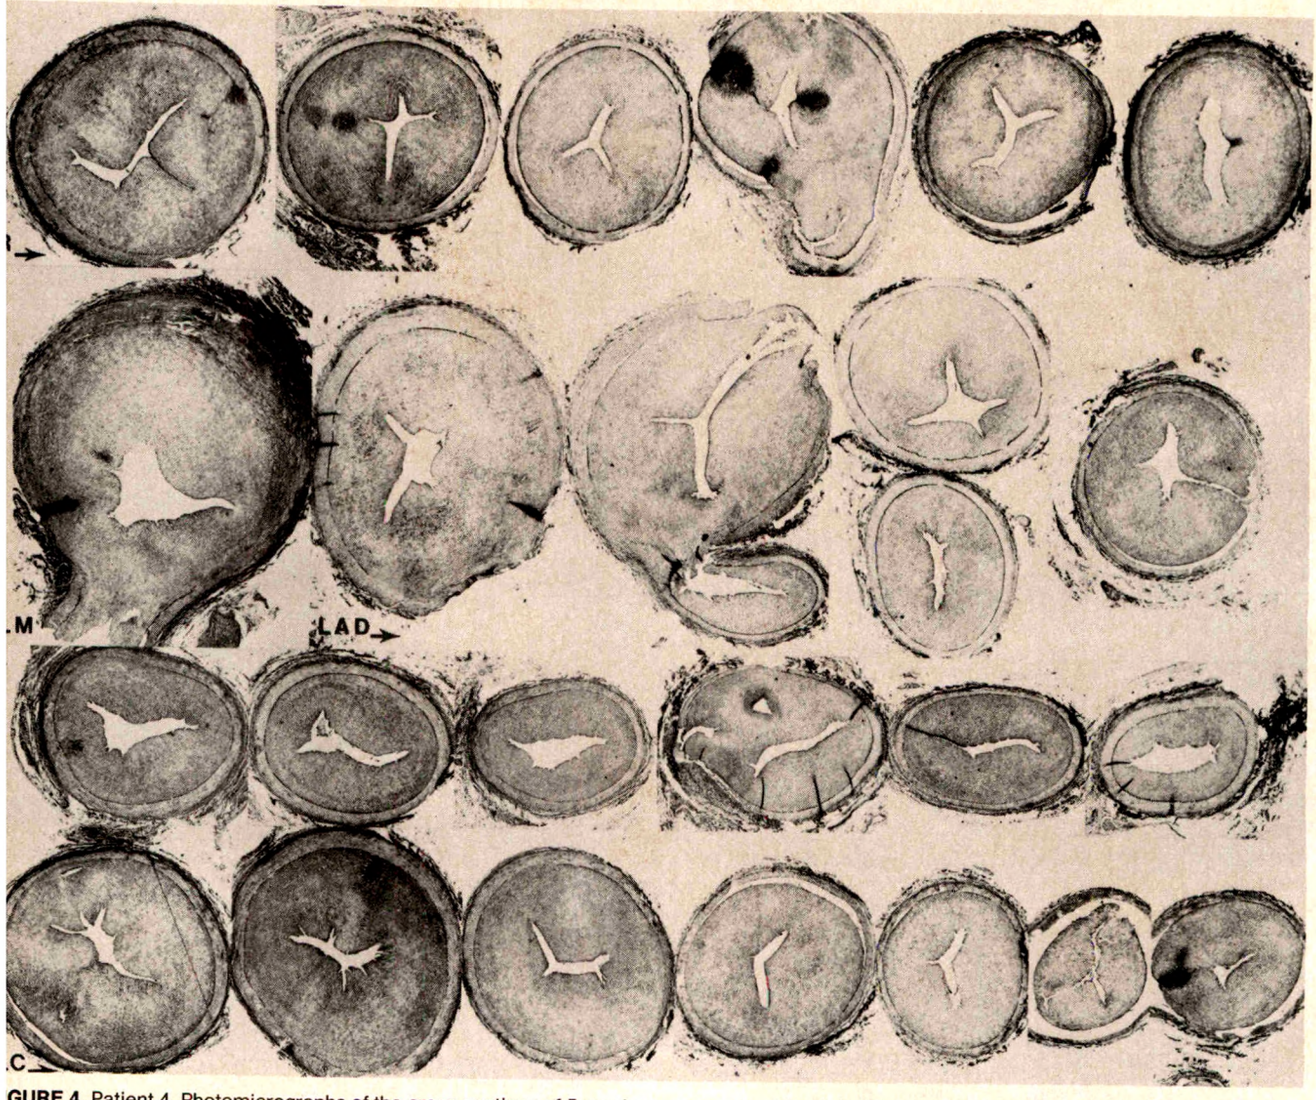
5	0	0	0	19	19	76	4.0
6	0	14	18	0	32	82	2.6
Total	9 (5%)	39 (21%)	59 (32%)	75 (42%)	182 (100%)	570	3.2

* Sum derived by assigning a number to each segment in each of the four categories of cross-sectional area (XSA) narrowing as follows: 1 = 0 to 25 percent narrowing; 2 = 26 to 50 percent; 3 = 51 to 75 percent; and 4 = 76 to 100 percent.

† Number derived by dividing the total number of 5 mm coronary segments per patient into the total score per patient.

four patients all four major coronary arteries, including the left main, were narrowed to this degree. Analysis of the degrees of narrowing of each 5 mm long segment of each of the four coronary arteries from each of the six patients disclosed that 75 (42 percent) of the 182 segments were narrowed 76 to 100 percent in cross-sectional area, including 14 (8 percent) that were narrowed 96 to 100 percent. Of the total group of 182 coronary segments, 134 (73 percent) were narrowed greater than 50 percent in cross-sectional area. To emphasize further the diffuse extent of the coronary narrowing, only 9 (5 percent) of the 182 coronary segments were narrowed 25 percent or less in cross-sectional area. The extent of the coronary narrowing is especially noteworthy in view of the young age of the patients (mean age 9 years, range 3 to 16) and the absence of clinical evidence of myocardial ischemia in all six patients or necropsy evidence of left ventricular fibrosis or necrosis in five of the six patients. The Hurler syndrome appears to be the cause of the most severe coronary narrowing in the first 2 decades of life.

Comparison with arteriosclerotic coronary disease: The extent and severity of the coronary narrowing in our six patients with the Hurler syndrome are similar to those observed at necropsy in adults with fatal coronary heart disease. Of 116 adult patients with fatal coronary atherosclerosis studied in our laboratory by an identical quantitative approach, the percent of 5 mm coronary segments narrowed 76 to 100 percent in cross-sectional area by atherosclerotic plaque in various groups of patients was as follows: sudden coronary death, 36 percent[8]; acute transmural myocardial infarction, 34 percent[9]; unstable angina pectoris, 47 percent[10]; healed myocardial infarction with chronic, eventually fatal congestive cardiac failure, 29 percent[11] and healed myocardial infarction with asymptomatic course after healing of the acute infarction and noncardiac death, 32 percent.[12] Thus, the extent of the se-



GURE 4. Patient 4. Photomicrographs of the cross sections of 5 mm long segments of the right (R), left main (LM), left anterior descending (LAD) ıd left circumflex (LC) coronary arteries in a 9 year old boy (A66-199) with the Hurler syndrome. The residual lumens are more or less centrally cated.

vere coronary narrowing in our patients with the Hurler syndrome was identical to that in our necropsy patients with unstable angina pectoris, which was the largest subset of adult patients with coronary disease. In contrast, however, to the 116 patients with coronary atherosclerosis, all of whom had clinical evidence of myocardial ischemia, none of our patients with the Hurler syndrome had such evidence even though nearly 50 percent of the lengths of their major coronary arteries was 76 to 100 percent narrowed in cross-sectional area, and only 1 of these patients had a left ventricular scar, and it was small and subendocardial.

In addition to the unique composition of the luminal material in our patients with the Hurler syndrome, the location of the residual lumens was quite different from that observed in patients with atherosclerotic coronary disease. In all of the latter patients, the lumens of the narrowed coronary arteries were eccentrically located at some point so that some portions of the arterial lining were not covered by atherosclerotic plaque. In our patients with the Hurler syndrome, the lumen in every 5 mm segment of coronary artery was centrally located or nearly so, and all portions of the arterial lining were covered by the Hurler-type plaque.

Two dimensional sector scan echocardiography was used to evaluate the morphologic characteristics of the surgically revised atria in 17 patients with d-transposition of the great arteries who had undergone the Mustard operation. Echocardiographic imaging of the atria was obtained from various planar projections. Dimensional measurements of various segments of the systemic and pulmonary venous atria were obtained in each patient. Correlative hemodynamic, angiographic, postmortem and echocardiographic data showed that seven patients (Group I) had no structural abnormalities of the atria. These 7 patients served as controls for 10 other patients with structural abnormalities of the surgically created atria. One patient (Group II) showed stenosis of the junction of the superior vena cava and systemic venous atrium compared with findings in the control group. Three patients (Group III) had significantly reduced echocardiographic dimensions of the junction of the anterior and posterior segments of the pulmonary venous atrium. Six patients (Group IV) had increased echocardiographic dimensions of all components of the pulmonary venous atrium due to tricuspid regurgitation. These data show that qualitative and quantitative two dimensional sector echocardiography can reliably detect structural abnormalities of the surgically revised atria after the Mustard operation.

Echocardiography has proved an important method for diagnosing d-transposition of the great arteries[1] and provides qualitative and quantitative assessment of associated lesions.[2,3] Indirect echographic criteria for estimating hemodynamic variables such as pulmonary arterial[4,5] and left ventricular pressures[6] are being developed. Two dimensional echocardiography has significantly improved the ability to diagnose not only transposed great vessels but also associated lesions.[7–9] Direct inspection of the interatrial[8] and interventricular septum,[9] the left ventricular outflow tract,[9] the pulmonary arteries and their first branches,[7] ventricular chamber size and atrioventricular (A-V) alignment[9] can be made in real time motion.

After the Mustard operation the intraatrial baffle can be detected with M mode echocardiography, and quantitation of the newly created systemic and pulmonary venous atria has been reported.[10–12] However, only limited and relatively undefined segments of these atria are visualized on M mode echocardiography, and abnormalities such as superior and inferior vena caval or pulmonary venous atrial stenosis cannot be diagnosed.[13] The purpose of this study was to evaluate with sector scan echocardiography the morphologic characteristics of the pulmonary and systemic venous atria and the A-V valves in patients with d-transposition of the great arteries who had had the Mustard operation. Correlative angiographic and pathologic findings indicate that two dimensional echocardiography is capable of detecting abnormalities of these structures.

Methods

Study patients: Seventeen patients, aged 4 months to 17 years, with d-transposition of the great arteries who had undergone the Mustard operation are included in this study. Seven patients (Group I) had no hemodynamic, angiographic or echocardiographic evidence of atrial chamber abnormalities after the Mustard operation and were considered to have had an ideal repair (Table I). These seven patients were retrospectively selected to serve as control subjects matched for body surface area to the 10 patients with structural abnormalities of the atria after the Mustard procedure (Table II). One patient (Group II) had both superior vena caval and pulmonary venous atrial obstruction, three patients (Group III) had stenosis of the pulmonary venous atrium, and six (Group IV) had tricuspid regurgitation.

Echocardiography: All patients had hemodynamic and angiographic evaluation by cardiac catheterization (Tables III and IV). The echocardiographic examination was performed with the patient in the supine position and the examiner seated to the right. A phased array real time sector scanner (Varian Associates model 3000, 2.25 megahertz transducer) or a mechanical sector scanner (ATL model 315A) was employed. The images were recorded from several planar projections.[13,14] The direction of the transducer and echocardiographic sector beam movements (right, left, anterior, posterior and so on) are described with reference to the patient's body.

Sector imaging of the systemic venous atrium: Descriptively the systemic venous atrium was divided into superior and inferior vena caval segments and their respective isthmic connections to the main body of the systemic venous atrium (Fig. 1A). The transducer was placed at the suprasternal notch location with the sector beam oriented in the coronal plane of the body, and images of the aorta and the right pulmonary artery were initially obtained. The transducer

was then tilted anteriorly and the superior vena caval segment and the segment of the isthmus connecting it to the main systemic venous atrial chamber were visualized. Occasionally the inferior vena caval segment of the systemic venous atrium could also be imaged from this transducer location and sector beam plane (Fig. 1B). Quantitation of the various segments of the systemic venous atrium was done at peak systole. The diameters at various levels were measured at right angles to the approximate long axis of each segment, and an average of three to four measurements was obtained at each level.

The inferior vena cava and inferior vena caval segments of the systemic venous atrium could be well visualized from

IVS = intact ventricular septum; PDA = patent ductus arteriosus; SMTV = septal malattachment of tricuspid valve; other abbreviations as in Table III.

the subxiphoid location with the sector beam oriented in the sagittal plane (Fig. 1C). A rightward angulation and clockwise rotation of the sector beam with additional anterosuperior angulation was utilized to view the superior vena caval segments. The right border of the cardiac silhouette in this view was formed by the pulmonary venous atrium.

The superior vena caval segment could also be viewed from the subxiphoid location (Fig. 2). The imaging search was initiated by directing the sector beam in a horizontal (four chamber) plane. Anterosuperior angulation of the transducer beam imaged the pulmonary artery with its first branches arising from the left ventricle (Fig. 3B), and a rightward and further anterior angulation confirmed the position of the anterior aorta arising from the right ventricle. Continued rightward direction of the echocardiographic beam brought into view the superior vena caval segment and the isthmic segment to the systemic venous atrium. In this image view the pulmonary venous atrium lay rightward and inferior to these structures (Fig. 2).

The systemic venous atrium could also be viewed in the left ventricular long axis view obtained from the left parasternal transducer location (fourth to fifth intercostal space). The pulmonary artery and left ventricle were visualized first in the left ventricular long axis view. The isthmic segment of the systemic venous atrium was seen behind the pulmonary artery, and with superior and rightward angulation of the echocardiographic sector beam the superior vena caval segment of the systemic venous atrium could be visualized. At times the transducer had to be shifted to the lower left parasternal location (fifth to sixth intercostal space) to obtain this view.

In a short axis view from the left parasternal transducer location at the base of the heart (Fig. 4), the superior vena caval-isthmic segment of the systemic venous atrium was imaged behind the pulmonary artery and left ventricular outflow. The pulmonary venous atrium was well visualized and seen to be composed of a posterior segment with pulmonary veins and an anterior segment close to the tricuspid valve.

Imaging of the pulmonary venous atrium: An echocardiographic image obtained from the apical transducer location with the echocardiographic sector beam oriented in a horizontal (four chamber) plane was most useful for evaluating the pulmonary venous atrium. After the Mustard operation the pulmonary venous atrium is divided into a posterior segment adjacent to the pulmonary veins, an anterior segment adjacent to the tricuspid valve and an isthmus representing the junction between the anterior and posterior segments (Fig. 5 A and B). The isthmus was bounded medially by the intraatrial baffle and laterally by the free wall of the surgically created pulmonary venous atrium (Fig. 5C). These segments were measured at peak systole using the transverse diameters at right angles to the approximate long axis of each segment. An average of the three to four such measurements from different cardiac cycles was used (Fig. 5C).

The pulmonary venous atrium could also be evaluated from the subxiphoid transducer location using the four chamber view. The anterior and posterior orientation of the respective segments could be well seen (Fig. 6, D and E). The parasternal short axis view also delineates the anatomy of the pulmonary venous atrium as a transverse section close to the pulmonary artery and left ventricular outflow (Fig. 4).

Because the diagnosis of tricuspid insufficiency was suggested in some cases from the increased echocardiographic dimensions of the pulmonary venous atrium and because the morphologic substratum for tricuspid insufficiency in transposition of the great arteries has not been reported in detail,

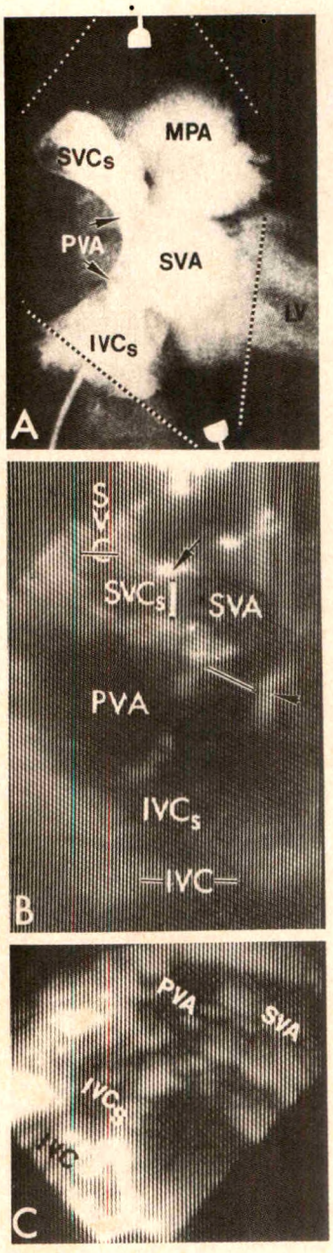

FIGURE 1. Case 16. Transposition of the great vessels and intact ventricular septum after Mustard operation. **A,** angiocardiogram of the systemic venous atrium (SVA), anteroposterior view. The systemic venous atrium is divided for descriptive purposes into superior (SVCs) and inferior vena caval segments (IVCs) with their connecting portions, termed the isthmus (**arrows**), joining them to the main body of the systemic venous atrium. The pulmonary venous atrium (PVA) lies to the right of the systemic venous atrium and forms the right border of the cardiac silhouette. **B,** sector scan, suprasternal view, with sector beam in the coronal body plane. The superior vena cava (SVC), the superior vena caval segment of the systemic venous atrium, the connecting isthmus (**upper arrow**) and the main body of the systemic venous atrium are well visualized. The inferior vena caval segment and its isthmus (**lower arrow**) are unusually well visualized in this patient. The pulmonary venous atrium forms the right border of the cardiac silhouette. **Bars** indicate the position of dimensional measurements of these segments which are made approximately at right angles to the long axis of each segment. **C,** the inferior vena caval segment and isthmus are best visualized from the subxiphoid transducer position with the sector beam in the sagittal body plane and tilted superiorly in a rightward direction. MPA = main pulmonary artery.

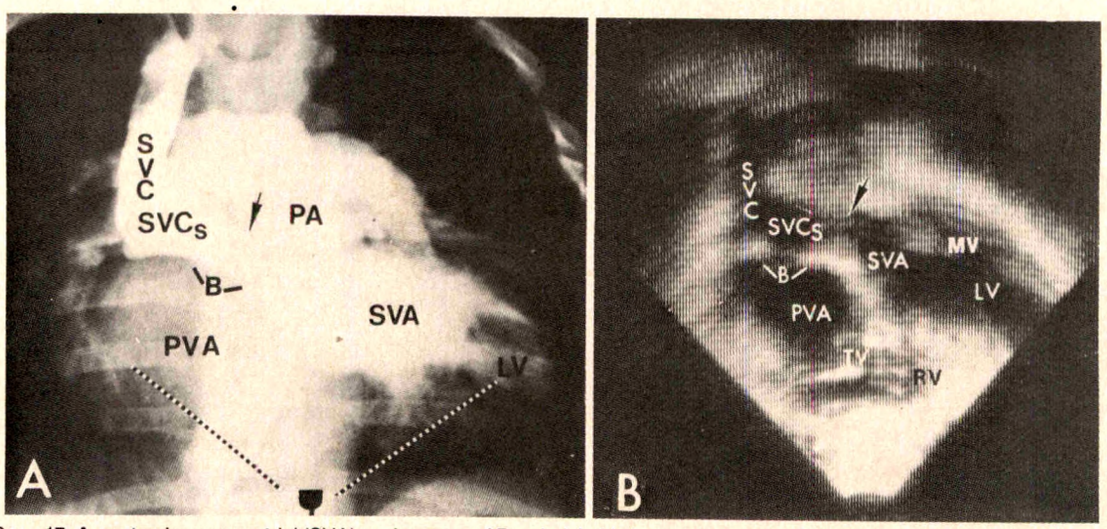

FIGURE 2. Case 17. **A,** systemic venous atrial (SVA) angiogram and **B,** subxiphoid view sector scan with sector beam directed rightward and slightly anteriorly. The superior vena caval segment (SVCs) and isthmus (**arrow**) can also be imaged from this sector projection. The position of the superior vena caval segment portion of the intraatrial baffle (B) separating the segment from the surgically created pulmonary venous atrium (PVA) is well defined. LV = left ventricle; MV = mitral valve; PA = pulmonary artery; RV = right ventricle; SVC = superior vena cava; TV = tricuspid valve.

an autopsy study of the tricuspid valve was made in 50 hearts with complete d-transposition, 20 hearts with an intact ventricular septum, 20 hearts with a ventricular septal defect and 10 hearts with left ventricular outflow stenosis with or without a ventricular septal defect.

Validation of findings: Validation of the two dimensional echocardiographic scan structure identification in this study was achieved by (1) correlating the angiographic and echocardiographic appearances of these atria in each patient, (2) performing echocardiographic contrast studies during cardiac catheterization, in one patient with injection of indocyanine green into the systemic venous and pulmonary venous atria (Fig. 6), and (3) performing pathologic, echocardiographic and angiographic correlations in two patients (Fig. 7).

Results

Group I: The sector scans of patients with an ideal repair (Group I) showed that the dimension of the superior vena caval-isthmic segment of the systemic venous atrium was narrower (0.82 ± 0.23 cm) than that of the superior vena caval segment (1.13 ± (0.34 cm) (Table I). These patients showed no significant (2 mm Hg or less) pressure gradient at either the superior or inferior vena caval junction with the systemic venous atrium. The inferior vena caval segment measurement was the largest of the various systemic venous atrial segments when quantitated with the subxiphoid scan (1.32 ± 0.53 cm).

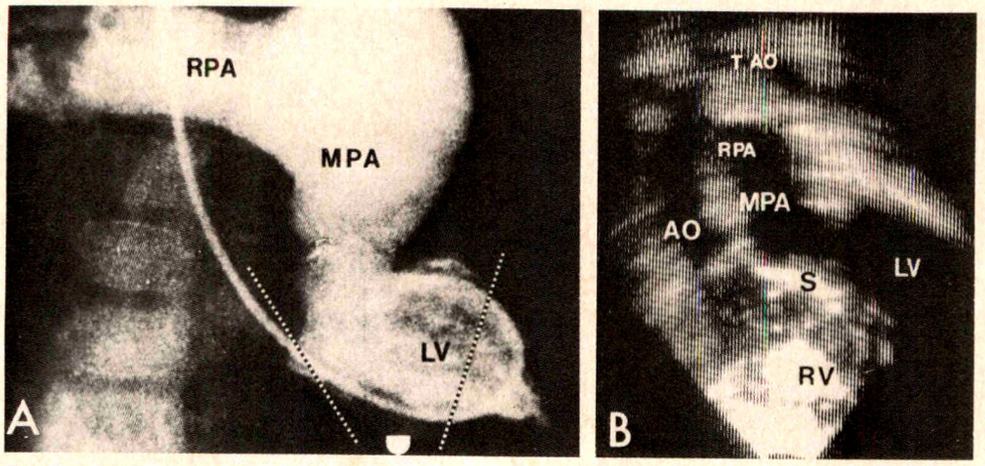

FIGURE 3. Case 9. **A,** left ventricular angiogram and **B,** subxiphoid view sector scan. Imaging of the superior vena caval segment of the systemic venous atrium is begun by obtaining a four chamber image and orienting the sector beam in the horizontal plane. With superior and anterior tilting of the echographic beam, the origin of the pulmonary artery (MPA) from the left ventricle (LV) and its branches can be defined. In this patient, the origin of the aorta (AO) from the right ventricle (RV) is unusually well visualized. Further anterior and rightward beam angulation from this position shows the superior vena caval segments and the systemic venous atrium (Fig. 2B). RPA = right pulmonary artery; S = interventricular septum; TAO = transverse aorta.

In Group I the dimensions of the anterior segments of the pulmonary venous atrium (1.98 ± 0.40 cm) were slightly larger than those of the posterior (1.83 ± 0.37 cm) or isthmic segments (1.38 ± 0.26 cm) (Table I). The isthmus was the narrowest segment, with the narrowing caused by rightward and ventral bulging of the intraatrial baffle. Angiographically, a mild waist in the pulmonary venous atrium was noted at this site; however, no pressure gradient was recorded at the isthmus in any of these patients.

Group II: Only one patient (Group II, Case 8) showed angiographic and hemodynamic evidence of stenosis of the superior vena caval-isthmic segment. The appearance of the suprasternal and subxiphoid sector scans correlated well with the angiographic appearance (Fig. 8). The dimension of the isthmus was markedly smaller (0.3 cm) than that of the superior vena caval segment (1.2 cm), and at cardiac catheterization there was a mean pressure difference of 9 mm Hg across the isthmus between the superior vena cava and the systemic venous atrium.

Group III: In Groups III and IV the superior vena caval-isthmic segment was slightly narrower than superior or inferior vena caval segments, similar to findings in the group with ideal repair (Group I), and none of these patients showed an abnormally large pressure difference across the isthmus.

In three patients (Group III), mild to moderate abnormal narrowing of the isthmic portion of the pulmonary venous atrium was noted both angiographically and echocardiographically (Fig. 9). In these three patients a mid diastolic murmur was audible at the mid and lower right sternal border and was considered to originate from within the narrowed pulmonary venous atrial isthmus. In Group I patients no such murmur was present. Sector scan measurements of the pulmonary venous atrial segments in these three patients showed significant narrowing of the isthmic portion (1.0 cm or less) (Table II). Hemodynamic studies in these patients performed a few years earlier than the echographic study demonstrated mild to moderate elevation of pulmonary arterial wedge pressure which, in the absence of ostial stenosis of the pulmonary veins, reflects the pressure of the posterior segment of the pulmonary venous atrium (Table IV). The degree of obstruction of the pulmonary venous atrium was not considered sufficient to require additional surgery in any of these patients.

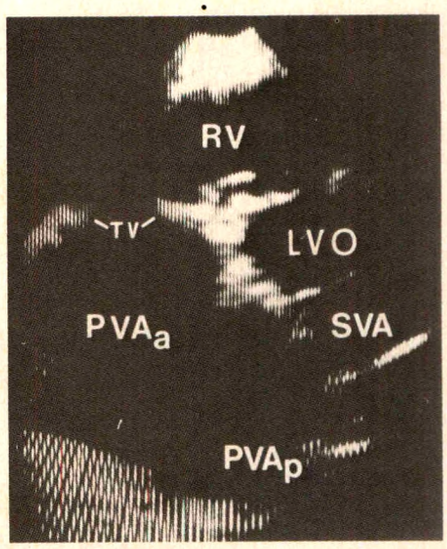

FIGURE 4. Case 15. Two dimensional sector scan, short axis view, recorded from the base of the heart at the parasternal location. A small segment of the systemic venous atrium (SVA) is seen behind the left ventricular outflow tract (LVO). The posterior (PVA_p) and anterior segments (PVA_a) of the pulmonary venous atrium are imaged in this view. RV = right ventricle; TV = tricuspid valve.

Group IV: Tricuspid regurgitation (Group IV) was established on the basis of hemodynamic and angiographic evidence in six patients. The sector scan dimensions of all segments of the pulmonary venous atrium in this group were increased and the mild isthmic narrowing noted in the control patients (Group I) was not present (Table II). In two of these patients prominent systolic pulsation of the pulmonary venous atrium

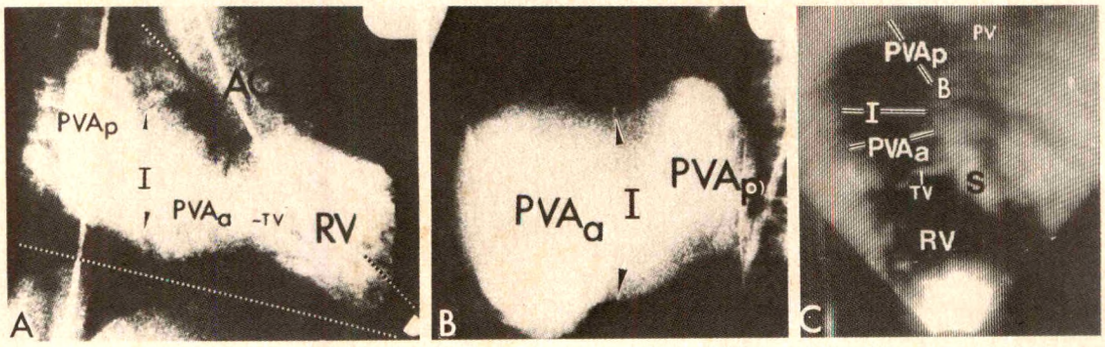

FIGURE 5. Case 12. **A**, right ventricular (RV) angiogram, anteroposterior view; **B**, pulmonary venous angiogram, lateral view; and **C**, foreshortened apical view sector scan of a patient with tricuspid regurgitation. The pulmonary venous atrium (PVA) is divided into a posterior segment (PVA_p) adjacent to the pulmonary veins and an anterior segment (PVA_a) adjacent to the tricuspid valve (TV) with a connecting isthmic portion (I). Pulmonary veins (PV) and the convex bulge of the intraatrial baffle (B) are well visualized in **C**. **Bars** indicate the site of transverse diameter measurements of these segments. AO = aorta; RV = right ventricle; S = interventricular septum.

was noted extending back posteriorly as far as the pulmonary veins. The angiographic and echocardiographic images of the pulmonary venous atrium were easily correlated (Fig. 10).

Preoperatively, five patients had a ventricular septal defect, two had subpulmonary stenosis and one patient had an intact ventricular septum with subpulmonary stenosis. Clinically, a pansystolic murmur was noted at the lower left sternal and xiphoid areas with accentuation in intensity during inspiration. Moderate to marked cardiac enlargement was evident in chest roentgenograms. Compared with findings in the normal control patients, right ventricular end-diastolic pressure was increased (Table IV). Right ventricular angiograms showed moderate to severe tricuspid insufficiency, and a dilated pulmonary venous atrium was noted in all. In order to achieve a satisfactory patch closure of the ventricular septal defect, the tricuspid valve was detached and subsequently reattached to the rim of the ventricular septal defect in three patients. One of the six patients with tricuspid insufficiency had an intact ventricular septum; the insufficiency was secondary to severe right ventricular dysfunction (angiographic ejection fraction 27 percent). On two dimensional sector scans in five patients, the tricuspid valve closure was abnormally horizontal (Fig. 10 top, B) in contrast to normal oblique tricuspid valve apposition. No definite systolic separation of the leaflets could be observed. In the sixth patient, the septal leaflet of the tricuspid valve was immobile because of its incorporation within the patch used to close the ventricular septal defect.

Postmortem study of the tricuspid valve: Additional postmortem study of the tricuspid valve in complete transposition with or without operative intervention revealed the following: Of the 20 heart specimens without ventricular septal defect, 7 (35 per-

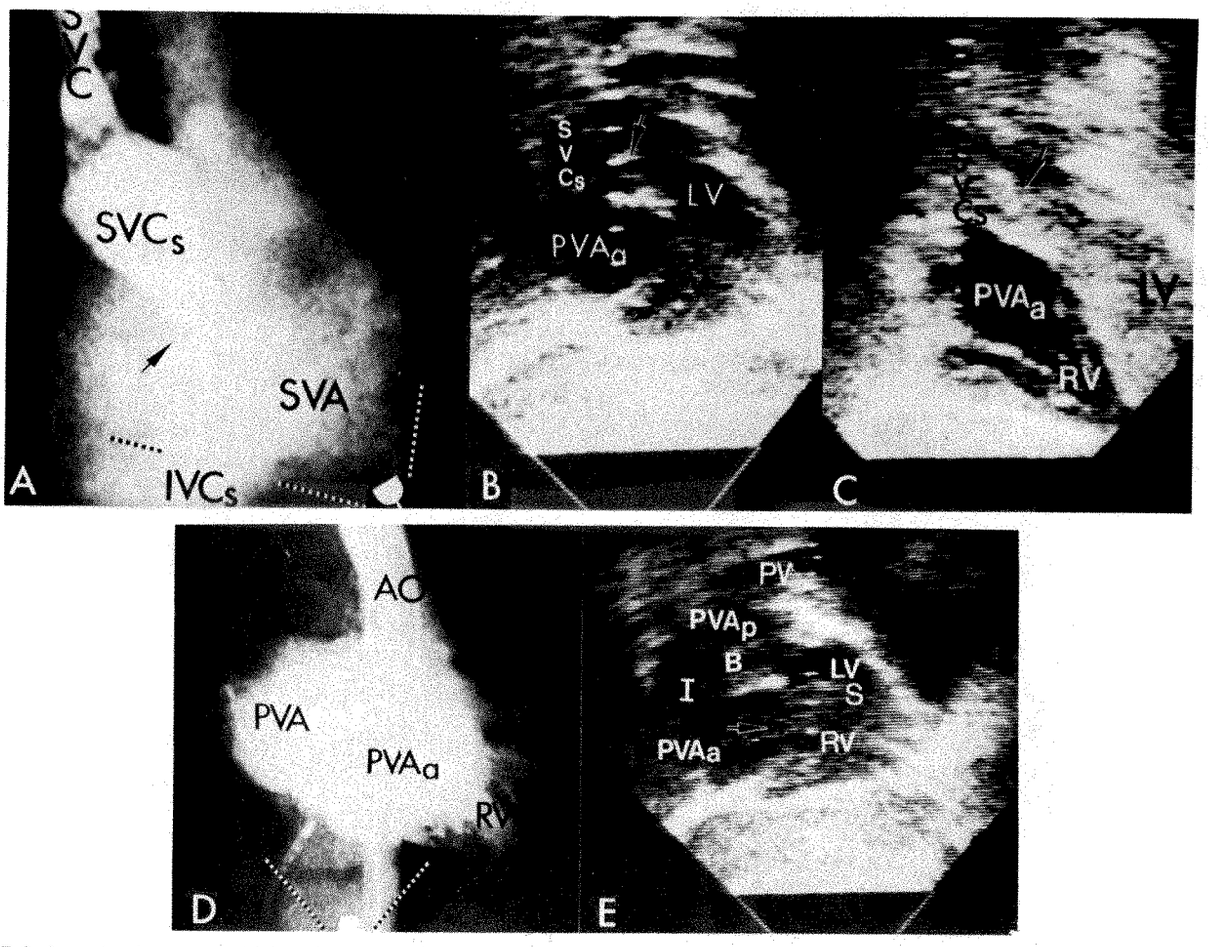

FIGURE 6. A, systemic venous atrial angiogram, anteroposterior view, and **B**, subxiphoid sector scan view of the superior vena caval segment SVCs) recorded during cardiac catheterization in an additional patient not included in the study. **A**, slight narrowing of the isthmus is noted (**arrow**); **3**, a faint catheter image is also noted within the isthmus. **C**, injection of indocyanine green in the superior vena cava opacifies the superior vena caval segment and the left ventricle (LV) and confirms the identification of these structures. **D**, pulmonary venous atrial (PVA) angiogram, anteroposterior view, and **E**, subxiphoid sector echocardiogram (four chamber view). Injection of indocyanine green into the right ventricle (RV) shows regurgitation of echocardiographic contrast material into the dilated anterior segment of the pulmonary venous atrium (**arrow**) and confirms the identity of these structures. Abbreviations as in Figure 5.

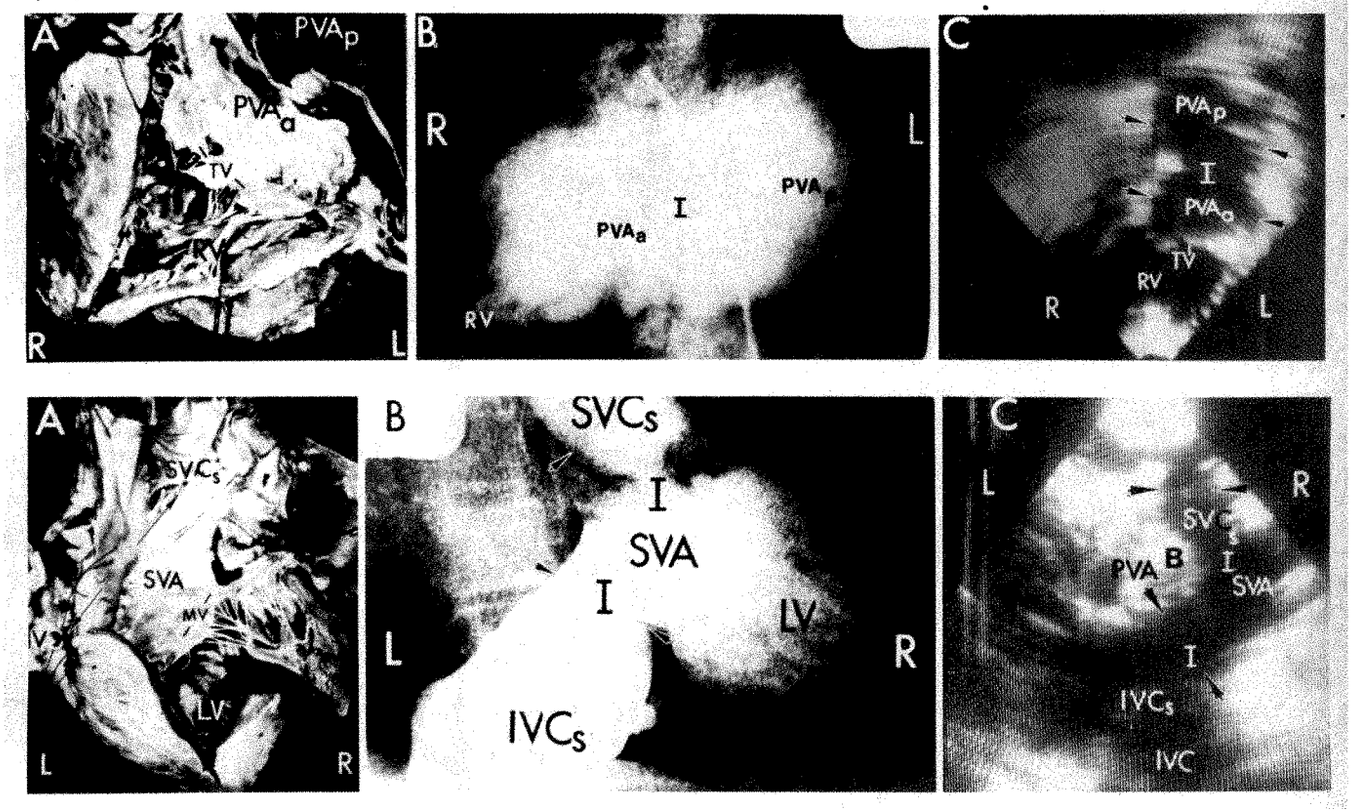

FIGURE 7. Case 14. **Top panel. A,** postmortem heart specimen; **B,** pulmonary venous angiogram (anteroposterior view); and **C,** sector scan, apical view, correlating the morphologic features of the pulmonary venous atrium with transposition of the great arteries and mirror-image dextrocardia. Severe tricuspid insufficiency developed after the Mustard operation due to a tricuspid valve leaflet disruption by the ventricular septal defect patch closure. All segments of the pulmonary venous atrium (PVA) and the isthmus (I) are grossly enlarged. Malapposition of the tricuspid valve (TV) can be seen on the sector scan. **Bottom panel. A,** postmortem heart specimen; **B,** systemic venous angiogram; and **C,** sector scan, suprasternal view with echocardiographic beam in the coronal body plane correlating the morphologic features of the systemic venous atrium. Because the systemic venous atrium (SVA) in the pathologic specimen is viewed from the posterior aspect, the correlative angiogram and echogram are reversed for laterality matching. **Arrows** in **B** and **C** indicate some of the sites used for dimensional measurements. B = intraatrial baffle; L = left; R = right; other abbreviations as in Figures 1 and 4.

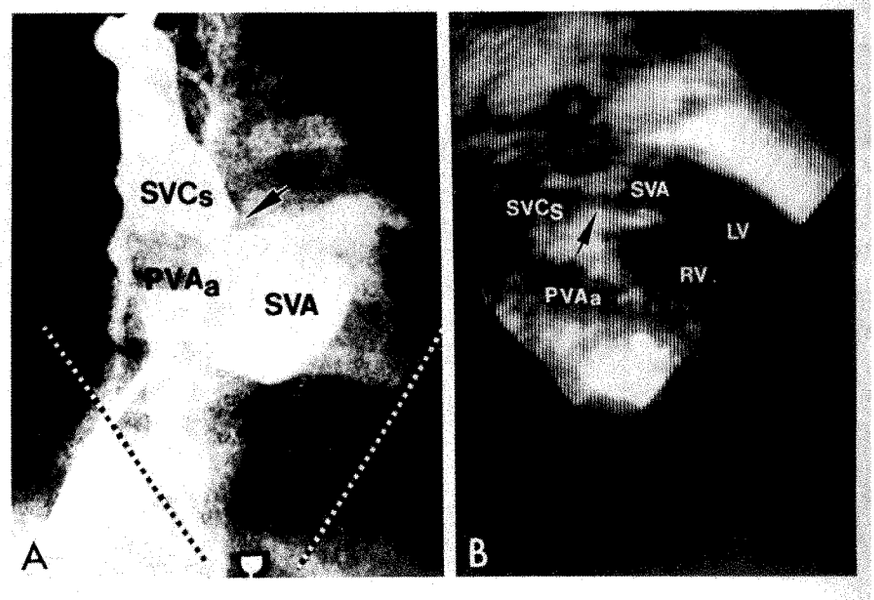

FIGURE 8. Case 7. **A,** systemic venous atrial angiogram and **B,** subxiphoid view sector scan illustrating severe stenosis of the superior vena caval segment (SVCs) isthmus (**arrows**). Abbreviations as in Figures 1 and 4.

cent) had anatomic abnormalities of the tricuspid valve; of 20 heart specimens with ventricular septal defect, 12 (60 percent) had abnormalities; and of 10 hearts with left ventricular outflow tract stenosis with or without ventricular septal defect, 4 (40 percent) had abnormalities of the tricuspid valve. Certain abnormalities were common to all three groups. The medial leaflet was attached by papillary muscles either to the septum or the septal band. The medial and inferior leaflets were often not sharply demarcated from each other, being more or less one leaflet (mitralization). Occasionally, the medial and anterior leaflets were fused. The anterior leaflet was sometimes divided into two leaflets. In one patient with a ventricular septal defect, tricuspid insufficiency was attributed to abnormal plastering of the medial portion of the anterior tricuspid leaflet against the ventricular septum. All tricuspid valves showed increased hemodynamic change.[15]

The autopsy patient with marked tricuspid insufficiency diagnosed with echocardiography (Fig. 7) had mirror-image dextrocardia with a large ventricular septal defect and previous Mustard operation. At autopsy the tricuspid orifice was enlarged. Each leaflet was divided into two parts, and there were two papillary muscles for each of the medial and inferior leaflets.

Discussion

Detection of stenosis and dilatation of the aorta: Our study shows that two dimensional echocardiography can be used to assess qualitatively and quantitatively the morphologic characteristics of the newly created systemic and pulmonary venous atria in patients with transposition of the great arteries after the Mustard operation. Although quantitation of anatomically bizarrely shaped atria may be subject to interobserver variability, this approach has prospectively helped us to detect stenosis and pathologic dilatation of these atria. The site and severity of these abnormalities was shown to correlate accurately with the angiographic appearances. Longitudinal follow-up may then be particularly facilitated by this noninvasive means so that progression of the lesions can be assessed during growth.

Only one patient in our study showed superior vena caval obstruction at the superior vena caval-isthmic junction,[16–18] which is the most likely site of stenosis in the systemic venous atrium. The slightly increased pressure in the superior vena cava did not necessitate revision of the atrial repair. We have not encountered an example of inferior vena caval-isthmic stenosis to date.

Stenosis of the pulmonary venous atrium[19–21] *was noted in three patients,* and was hemodynamically mild in one and moderate in two. The site of the stenosis was the isthmus between the posterior and anterior segments where the intraatrial baffle with its anterior and ventral bulge usually makes a waist in the pulmonary venous atrium. This seems to be the usual area of narrowing, and various surgical techniques have been used to enlarge the pulmonary venous atrium at this site by

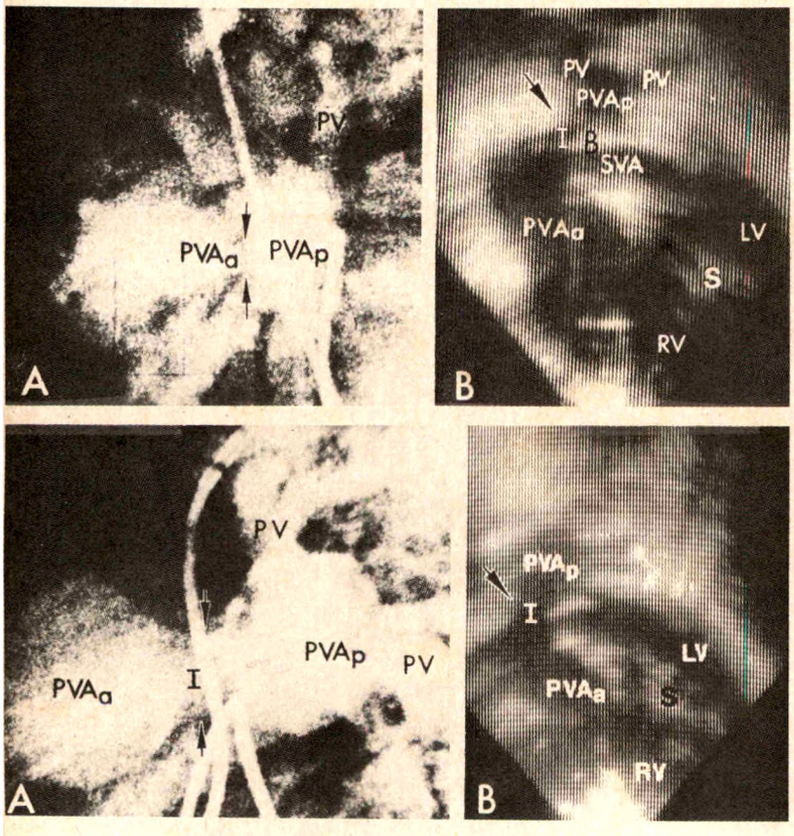

FIGURE 9. Top panel, Case 11. **A**, pulmonary venous atrial (PVA) angiogram, lateral view; and **B**, sector scan, apical view. Moderately severe stenosis (**arrows**) of the isthmus (I) is shown, giving the pulmonary venous atrium an hourglass appearance. The pulmonary veins (PV) are clearly viewed in the sector scan and are unobstructed. **Bottom panel,** Case 9. **A**, angiogram, lateral view, and **B**, sector scan, apical view, illustrating a lesser degree of isthmic stenosis of the pulmonary venous atrium (**arrows**). Abbreviations as in Figures 1 and 4.

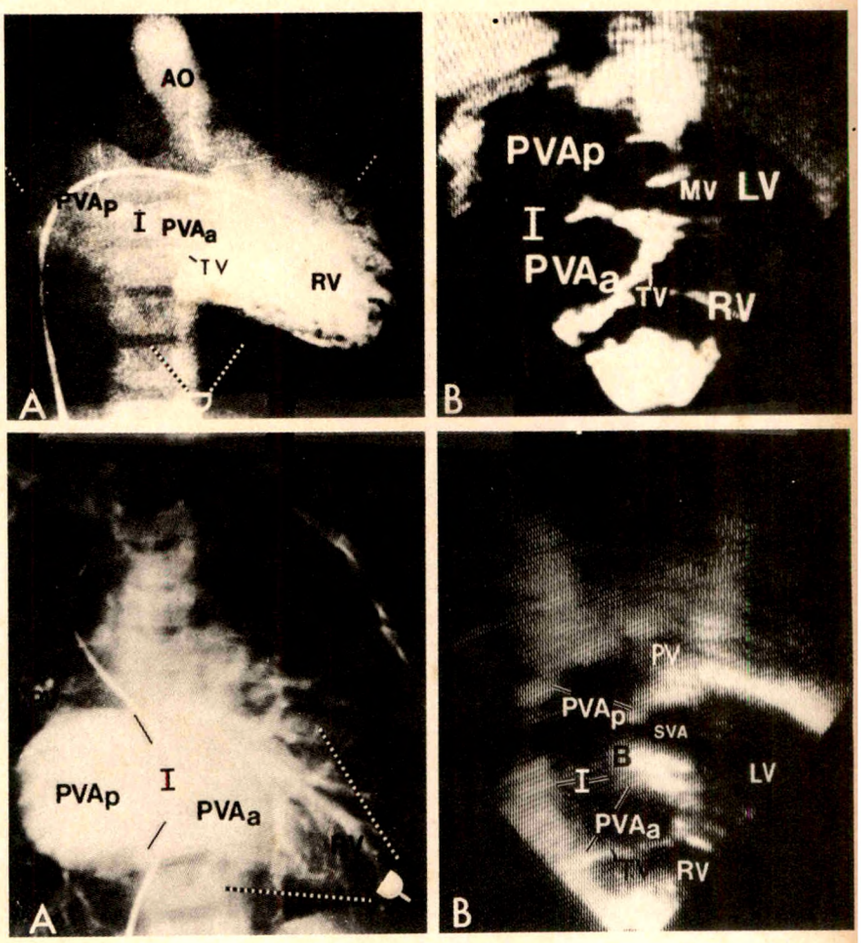

FIGURE 10. Top panel, Case 16. **A,** pulmonary venous angiogram and **B,** subxiphoid sector scan with severe tricuspid regurgitation requiring tricuspid valve (TV) replacement. Note almost horizontal malapposition of tricuspid valve leaflets in the echocardiogram and markedly enlarged segments of the pulmonary venous atrium (PVA). **Bottom panel,** Case 17. **A,** angiogram and **B,** sector scan, apical view, illustrating another patient with marked dilatation of the pulmonary venous atrial segments due to tricuspid regurgitation, who also required tricuspid valve replacement. Abbreviations as in Figures 1 and 4.

trimming the baffle and by patch enlargement of the lateral wall of the pulmonary venous atrium.[22,23] The hemodynamic severity of the pulmonary venous atrial stenosis was mild, as reflected by mildly elevated pulmonary arterial pressures, and the degree of stenosis was not considered significant enough to require reoperation.

Morphologic correlations between the lateral view angiograms and sector echocardiograms at the site of stenosis were good. However, angiographic quantitation of the narrowed segment was difficult and less accurate than the sector scan image quantitation because of superimposition of the anterior and posterior segments of the pulmonary venous atrium in the anterior and to some extent on the lateral angiogram, which obscured the isthmic region. The isthmic site on echocardiographic images was displaced posteriorly in the three Group III patients compared with the site in the control patients. This indicates that some cases of late stenosis of the pulmonary venous atrium may be due to contraction of the intraatrial baffle, which would result in the posterior displacement (closer to the pulmonary veins) of the isthmus.[20] Pulmonary veins could be clearly seen in all 17 patients and were unobstructed in the aforementioned patients. The diameter of the pulmonary venous isthmus was 0.9 to 1.0 cm, and this narrowed "waist" segment presumably was responsible for a mid diastolic murmur in these three patients. The continuous murmur recently described with pulmonary venous atrial stenosis[24] after the Mustard operation may be a late result of continued stenosis and marked reduction in the size of the posterior segment, which would result in loss of compliance and continued generation of systolic and diastolic pressure gradients similar to those with cor triatriatum.

Tricuspid regurgitation: This abnormality was confirmed at cardiac catheterization in each of our six Group IV patients and was shown to lead to a grossly enlarged pulmonary venous atrium with dilatation in all of its segments. The echocardiographic diagnosis of tricuspid regurgitation is indirect because regurgitation of the blood into the pulmonary venous atrium cannot be observed directly. Nonetheless, grossly increased dimensions of the pulmonary venous atrium with systolic pulsations and abnormalities of the tricuspid valve were associated in our study with angiographically proved tricuspid regurgitation. The mild narrowing of the pulmonary venous chamber isthmus noted in the control group was less obvious in these cases. In four cases the apposition of the tricuspid valve was almost horizontal and suggested that such apposition was due to dilatation of the right ventricle. Systolic pulsation of the posterior as well as the anterior segments of the pulmonary venous atrium suggested a marked degree

f tricuspid regurgitation. In one postoperative patient mmobilization of the septal leaflet of the tricuspid valve vas thought to lead to malapposition of the tricuspid eaflet resulting in tricuspid regurgitation. The recently leveloped technique of Doppler echocardiography ould be used for confirmation of tricuspid regurgitation y showing systolic turbulence in these dilated atria.

The cause of the tricuspid insufficiency in complete l-transposition is probably related to pre-, intra- and ostoperative factors.[25,26] Our pathologic studies show hat in nonsurgically treated complete transposition here is a marked tendency for abnormality in the entricular attachments of the tricuspid valve. Superposed on this is the factor of altered valve structure onsequent to hemodynamic stresses imposed on a ricuspid valve structure by systemic resistance. In some ases of transposition without ventricular septal defect, ricuspid insufficiency may develop because of the aforementioned factors exacerbated by increasing longevity. Where there is a ventricular septal defect there is a still greater tendency for the tricuspid valve to show abnormality. Here there may be malattachments of the tricuspid valve to the rim of the defect in some cases, as was demonstrated before surgical repair in four of our patients. There are also usually increased hemodynamic changes because of the defect. Intra- and postoperative damage to the tricuspid valve may result coincident with surgical repair (patching) of the ventricular septal defect when leaflet malattachments extend onto or across the rim of the defect. Thus, operative intervention in closure of the ventricular septal defect obviously can exacerbate the tendency toward tricuspid insufficiency. On occasion intrinsic right ventricular dysfunction may lead to tricuspid insufficiency, as was observed in one of our patients with an intact ventricular septum.

In angina pectoris...

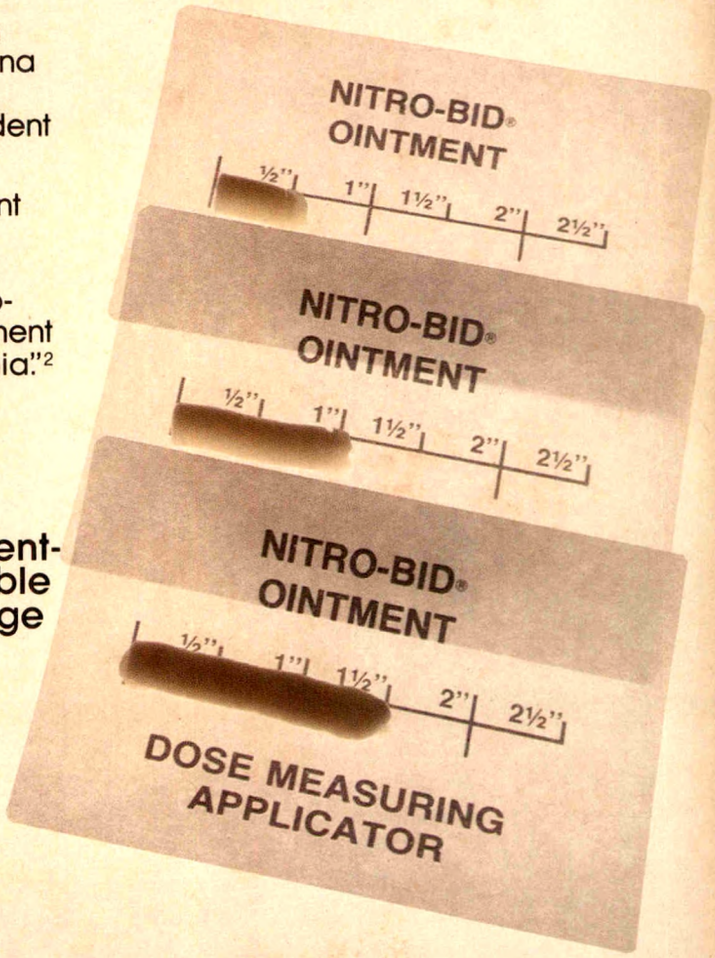
NITRO-BID®
(2% nitroglycerin)
Transdermal Ointment

For prolonged prophylactic action

"Cutaneous administration of Nitroglycerin ointment (NITRO-BID®) in patients with angina pectoris exhibits prolonged action with evidence of pharmacological activity evident up to eight hours after application."[1]

"...data indicate that nitroglycerin ointment (NITRO-BID®) exerts profound reduction of peripheral arteriolar and venous tone with resultant alterations in left ventricular hemodynamic variables which afford enhancement of exercise tolerance and reduced ischemia."[2]

Patient-titratable dosage



Brief Summary:

Description: Nitroglycerin 2% (glyceryl trinitrate) and lactose in a special absorptive lanolin and white petrolatum base.

Action: Nitroglycerin is continuously absorbed through the skin into the circulation, thus exerting prolonged vasodilator effects.

Indications: For the prevention and treatment of angina pectoris due to coronary artery disease.

Contraindications: In patients known to be intolerant of the organic nitrate drugs.

Warnings: In acute myocardial infarction or congestive heart failure, nitroglycerin ointment should be used under careful clinical and/or hemodynamic monitoring.

Precautions: Symptoms of hypotension, particularly when suddenly arising from the recumbent position, are signs of overdosage. When they occur, the dosage should be reduced.

Adverse Reactions: Transient headaches are the most common side effect, especially at higher dosages. Headaches should be treated with mild analgesics, and nitroglycerin ointment concentration reduced. Although uncommon, hypotension, an increase in heart rate, faintness, flushing, dizziness, and nausea may occur. These all are attributable to the pharmacologic effects of nitroglycerin on the cardiovascular system, but are symptoms of overdosage. When they occur and persist, the dosage should be reduced.

Dosage: Usual dose is 2 inches (50mm), as squeezed from the tube, every eight hours. Some patients may need 4 to 5 inches (100 to 125 mm) and/or application every four hours. Optimal dosage should be based upon clinical response, side effects, and effects of therapy upon blood pressure. Consult full product disclosure before prescribing.

THE NEW MICROTHIN™-P2... GUARANTEED SENSING

MICROTHIN-P2's sensing is so exceptional that, whenever you implant a MICROTHIN-P2 with a CPI® Porous Tip Lead, it is guaranteed. If any sensing difficulties develop, you'll receive immediate full credit for the MICROTHIN-P2.

CPI has recognized that efficient sensing is of paramount importance, and we've responded to that need with the MICROTHIN-P2. In fact, MICROTHIN-P2 addresses *all* the issues that are of prime importance in cardiac pacing:

- Proven reliability*
- The most useful programmable features - rate and energy output
- Superior sensing
- Lifetime warranty**
- Small size for patient comfort
- Easy, safe follow-up

Eight years of CPI experience prove that pacing can evolve... advance...become simpler yet superior. That's MICROTHIN-P2. It is the simple, effective solution for the majority of your pacemaker patients.

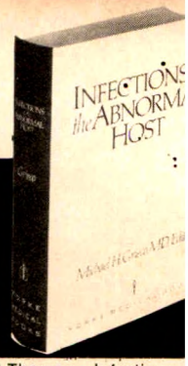
For single-rate demand pacing, ask your sales representative about MICROTHIN-D2.

*For a copy of CPI's "Seven Years of Reliability" report, contact your sales representative.

**The lifetime warranty option is not available in all countries. Contact your sales representative for full warranty information for your area.

CPI®

NOW AT YOUR FINGERTIPS ...the knowledge of world-renowned specialists to help you understand, diagnose, and manage infections which strike patients with: Diabetes / Alcoholism / Cancer / Drug Addiction / Rheumatic Disease / Uremia / Pulmonary Disease / Hepatic Insufficiency / Allograft Transplantation, etc., etc.



INFECTIONS IN THE ABNORMAL HOST

Edited by Michael H. Grieco, M.D.
Text by 47 Specialists. Illustrated with 147 Drawings and Photos, 78 in Full Color

Infections in the Abnormal Host discusses in 36 revealing chapters the mechanics of host defenses... the various underlying disorders and the latest treatments by chemotherapy, management of agranulocytosis, immunological reconstitution, passive and active immunotherapy, and immunostimulation.

Consultation and study of **Infections** will help you understand, diagnose, and manage the many infections which strike patients whose defense mechanisms are down.

Check this list of chapters

PART I HOST DEFENSES
• Introduction to the Abnormal Host and Complicating Infections • The Neutrophil in Host Defense: Congenital, Acquired and Drug-induced Abnormalities • The Complement System in Human Disease • Structure and Function of Immunoglobulins • Human Lymphocyte Subpopulations: Surface, Intracellular, Enzymatic Markers and Functions • Congenital and Acquired Primary Disorders of B and T Lymphocyte Function • Drug-induced B and T Lymphocyte and Monocyte Dysfunction • Cutaneous, Pulmonary, Gastrointestinal and Genitourinary Defense Mechanisms and Relationship to Nosocomial Infections • The Effects of Malnutrition on Host Responses and the Metabolic Sequelae of Infections • Humoral and Cellular Responses to Infection

PART II INFECTIONS ASSOCIATED WITH THE ABNORMAL HOST
• Pyogenic Bacterial Infections • Higher Bacterial and Fungal Infections • Mycobacterial Infections • Viral and Chlamydial Infections • Protozoal and Helminthic Infections • Infections Complicating the Transfusion of Blood, Blood Products, Animal Exposure and Animal Products • Infections Complicating the Alcoholic Host • Infections in Parenteral Narcotic and Drug Abusers • Infections Complicating Uremia and Organ Transplantation • Infections in Patients with Neoplastic Diseases • Infections Complicating Diabetes Mellitus • Diagnosis and Treatment of Diffuse Pneumonias • Host Deficiency States and Central Nervous System Infections • Genitourinary Infections • Infections Complicating the Rheumatic Diseases • Endovascular and Prosthetic Implant Infections • Intraocular Manifestations of Systemic Infections • Selected Histopathologic Responses • The Microbiology Laboratory in Diagnosis and Therapy • Infections Complicating Surgical or Functional Splenectomy and Gastrectomy

PART III MANAGEMENT
• Antimicrobial Therapy in the Compromised Host: Resistance, Pharmacology and Toxicity • Chemotherapy for Viral and Chlamydial Infections • Chemotherapy for Protozoal and Helminthic Infections • Infection Prevention in Patients with Cancer and Granulocytopenia • Immunologic Reconstitution • Gamma Globulin and Vaccine Therapy • Index

THE ROGERS HEART FOUNDATION

...is pleased to announce our 1981 Continuing Education Meetings. To keep abreast of current cardiology, join us this year on the relaxing beaches of Florida; travel with us to Montreal, the largest French-speaking city outside France and see how French it is at heart, to the home of the world's most celebrated Barber where a combination of colour, drama and charm has given Seville a unique personality, or to Athens, cradle of our Western civilization where the tide of time has not extinguished its capital charm.

If you would like to be on the Rogers Heart Foundation's mailing list for all Continuing Education Meetings, fill out the form below and mail to Rogers Heart Foundation, St. Anthony's Hospital, 601 12th St. North, St. Petersburg, Florida 33705, (813—894-0790). Individual programs will be printed and available three to four months prior to date of each meeting.

6th ANNUAL SYMPOSIUM ON CARDIOVASCULAR NURSING
MAY 28-31, 1981
Sheraton Sand Key Hotel — Clearwater Beach, Florida
Fee: $150.00 (U.S.)
Directors: Henry J.L. Marriott, M.D., St. Petersburg, FL
Leo Schamroth, M.D., Johannesburg, South Africa
Faculty: International

14th ANNUAL PHYSICIANS WORKSHOP IN ELECTROCARDIOGRAPHY
JUNE 9-16, 1981
Los Lebreros Hotel — Seville, Spain
Fee: $150.00 (U.S.) Credit Hours 24
Directors: Henry J.L. Marriott, M.D., St. Petersburg, FL
Demetrio Sodi-Pallares, M.D., Mexico City
(This meeting will meet all requirements for overseas deductions for attending foreign conventions)

6th CANADIAN SUMMER WORKSHOP
JULY 18-21, 1981
Sheraton Mt. Royal — Montreal, Quebec
Fee: $150.00 (U.S.) Credit Hours: 24
Director: Henry J.L. Marriott, M.D., St. Petersburg, FL

19th ANNUAL SEMINAR IN CARDIOLOGY
SEPTEMBER 27 - OCTOBER 6, 1981
Astir Palace Hotel on Vouliagmeni Beach — Athens, Greece
Fee: $250.00 (U.S.) Credit Hours: 24
Director: Henry J.L. Marriott, M.D., St. Petersburg, FL
FACULTY
Dennis Cokkinos, Athens, Greece
Ronald Gibson, London, England
David Kelly, Sydney, Australia
Peter Nixon, London, England
Henry Wagner, Baltimore, MD
Leonard Gardberg, Winter Park, FL
John Goodwin, London, England
Richard Myler, San Francisco, CA
Robert O'Rourke, San Antonio, TX
David Spodick, Worcester, MA
Edith Gipstein, New London, CT
(This meeting will meet all requirements for overseas deductions for attending foreign conventions)

22nd ANNUAL WORKSHOP IN ELECTROCARDIOGRAPHY FOR NURSES AND PHYSICIANS
OCTOBER 15-19, 1981
Sheraton Sand Key — Clearwater Beach, Forida
Fee: $125.00 (U.S.) Credit Hours: 24
Director: Henry J.L. Marriott, M.D., St. Petersburg, FL

FERVESCENT TABLETS
LYTE/CL® 50 mEq—Fruit Punch and Citrus Flavors
ach effervescent tablet in solution supplies 50 mEq potassium chloride)

ESCRIBING CONSIDERATIONS

DICATIONS: K-LYTE/CL 50 mEq is an oral potassium supplement for therapy or prophylaxis of potassium deficiency. It is particularly useful when azide diuretics, corticosteroids, or severe vomiting and diarrhea cause excessive excretory potassium losses, and when dietary potassium is low efully monitored, K-LYTE/CL 50 mEq may also be useful for potassium administration where digitalis intoxication results in cardiac arrhythmias.

NTRAINDICATIONS: Impaired renal function with oliguria or azotemia; Addison's disease; hyperkalemia from any cause

ARNINGS AND PRECAUTIONS: Since the amount of potassium deficiency may be difficult to determine accurately, supplements should be administered with caution, and dosage adjusted to the requirements of the individual patient. Potassium intoxication rarely occurs in patients with normal kidney function. Symptoms of potassium intoxication are variable. They include listlessness, mental confusion, and tingling of the extremities. Frequent checks of the clinical status of the patient, ECG, and serum potassium level are desirable. In established hypokalemia, attention should also be directed toward other potential electrolyte disturbances. Potassium supplements should be given cautiously to digitalized patients and such patients should be monitored by ECG for cardiac irregularities. To minimize the possibility of gastrointestinal irritation associated with the oral ingestion of concentrated potassium salt preparations, **patients should be carefully directed to dissolve each dose completely in the stated amount of water.**

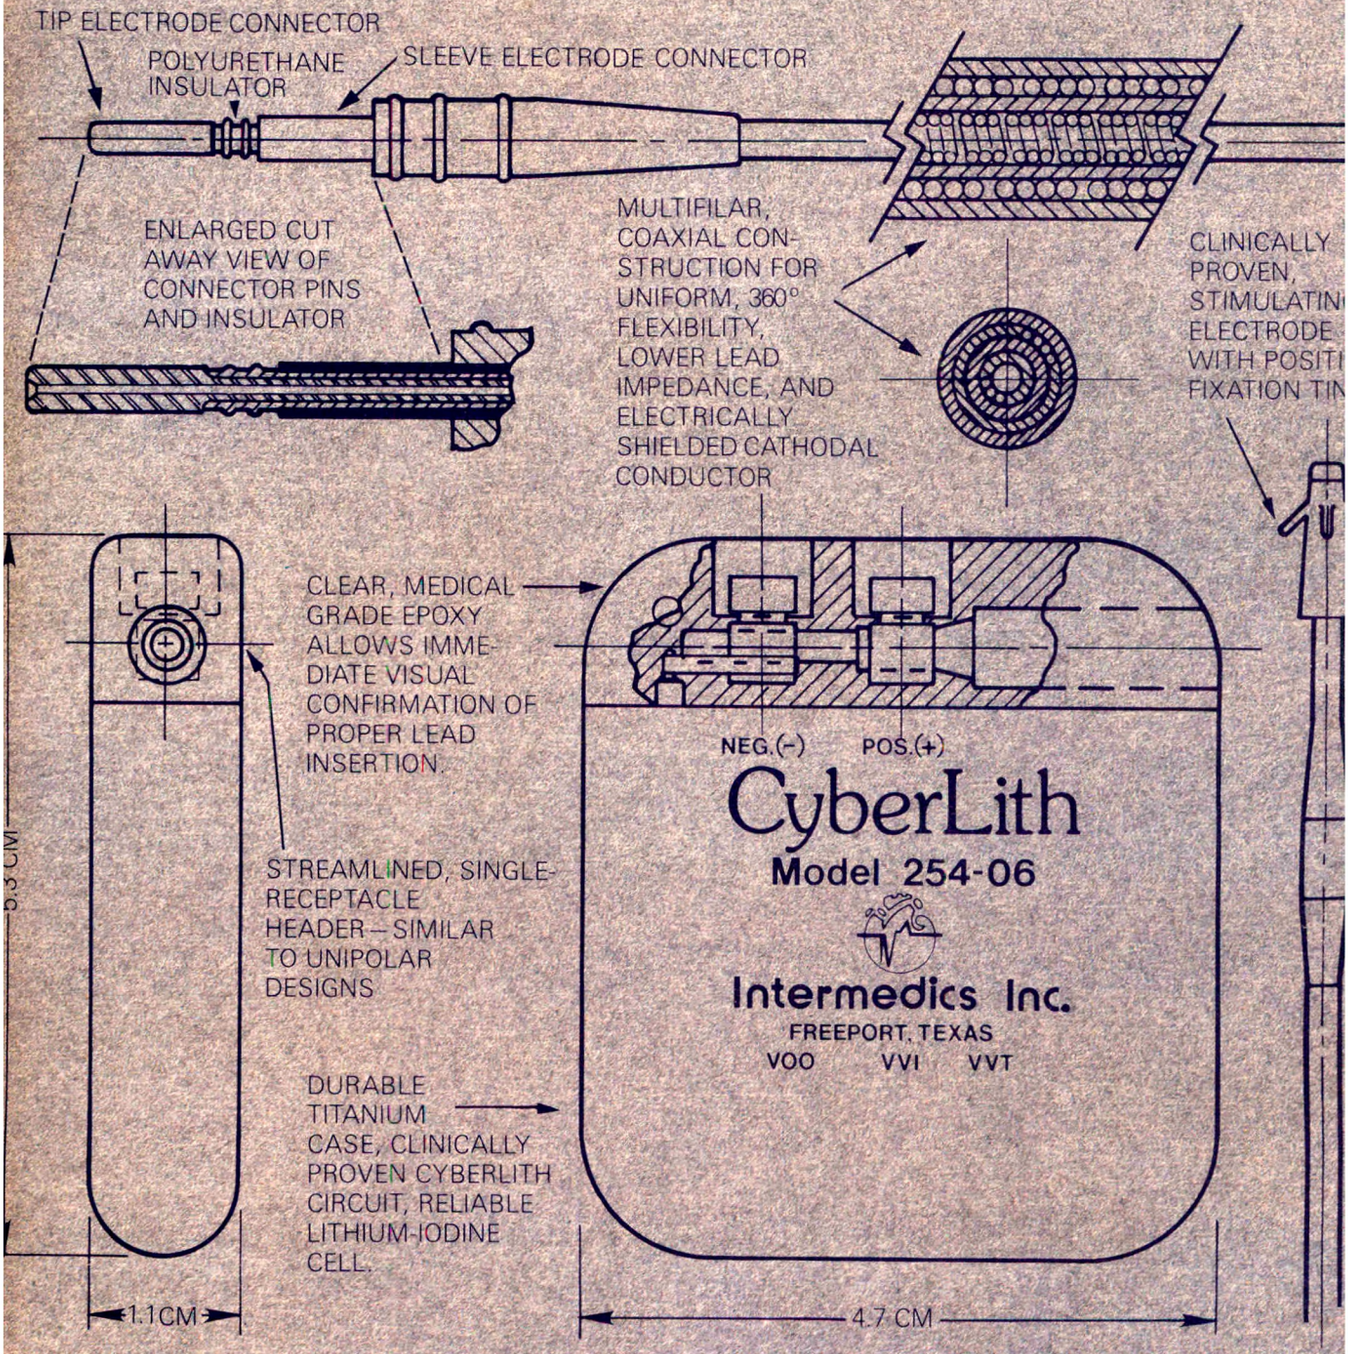
VERSE REACTIONS: Nausea, vomiting, diarrhea, and abdominal discomfort may occur with the use of potassium salts.

SAGE AND ADMINISTRATION: Adults: 1 tablet completely dissolved 1 to 2 times daily, depending upon the requirements of the patient: 1 tablet (50 mEq potassium chloride) in 6 to 8 ounces of cold or ice water. The normal adult daily requirement is approximately 50 mEq of elemental potassium. **TE: It is suggested that K-LYTE/CL 50 mEq be taken with meals and sipped slowly over a 5-10 minute period.**

W SUPPLIED: K-LYTE/CL 50 mEq effervescent tablets (fruit punch and citrus flavors) cartons of 30 and 100. Also available, K-LYTE/CL effervescent tablets (25 mEq fruit punch and citrus flavors) cartons of 30 and 250. Each tablet is individually foil wrapped.

Mead Johnson PHARMACEUTICAL DIVISION

Intermedics bipolar



Intermedics Pulse Generators

INDICATIONS AND CONTRAINDICATIONS

The indications for cardiac pacemaking are increasing as pacemakers become more sophisticated and as advanced methods for patient management become more widespread. Generally accepted indications for long-term cardiac pacing include but are not limited to: (1) sick sinus syndrome; (2) chronic, symptomatic drug-resistant sinus arrhythmias, including sinus bradycardia, sinus arrest, and sinoatrial (S-A) block as seen in sick sinus syndrome; (3) chronic, symptomatic second-degree or third-degree A-V block; (4) recurrent Adams-Stokes syndrome; (5) bradycardia-tachycardia syndrome; (6) symptomatic bilateral bundle branch block; and (7) hypersensitive carotid sinus syndrome(carotid sinus syncope). In addition, certain patients presenting with intractable, recurrent, congestive heart failure; cerebral or renal insufficiency; or recurrent, drug-resistant tachyarrhythmias who have been shown to benefit from temporary cardiac pacing are considered candidates for permanent cardiac pacemaking.

The indications for permanent pacing in the presence of acute myocardial infarction have not yet

ctreamlines pacing.

NEW, easy-to-use bipolar technology plus PROVEN CyberLith® circuitry.

The New Standard For Bipolar Pacing.

Intermedics in-line technology is an entirely new concept in bipolar pacing. It permits a bipolar pacing system to be as thin, small, and lightweight as most unipolar systems; it offers remarkable convenience and simplicity of use; and it provides unparalleled immunity to non-cardiac signals.

Exceptional Noise And Artifact Immunity.

Intermedics in-line bipolar concept has added an important dimension to the ability to reject undesired signals. The lead conductors are coaxial providing shielding all the way from the pulse generator to the ring electrode. The result is a clean, crisp intracardiac signal to the sensing circuitry of the pacemaker, free from unwanted noise or other artifacts. No other bipolar pacemaker available offers this advantage.

Simple, Convenient Implantation.

The CyberLith I model 254-06, the newest member of the CyberLith family of pacemakers, is the first multiprogrammable pacemaker to use the new in-line technology. A simple, in-line connector eliminates the bulky, bifurcated connectors in the pacemaker and the lead. The smaller, physiologically compatible pacemaker fits easily in the pocket.

Intermedics—On The Leading Edge Of Pacemaker Technology.

Innovation is not the only reason for selecting an Intermedics product. The CyberLith family of pacemakers is unsurpassed in clinical experience, proven performance and reliability.

To find out more about the new convenience of bipolar pacing, contact your Intermedics representative or call us toll-free at 800/231-2330.

been rigorously defined. Factors to be considered include the location of the myocardial infarct, the presence or absence of symptoms, ventricular rate, mechanism of the arrhythmias, and response to therapy. In general, symotomatic drug-resistant bradyarrhythmias which impair cardiac output are considered indications for pacing in patients with acute myocardial infarction, regardless of infarct location.

There are no known contraindications to the use of pacemakers as a medical method for control of heart rate. However, body rejection phenomena such as local tissue reaction or skin necrosis, muscle and nerve stimulation, embolism, and cardiac tamponade have been reported.

CAUTION: Federal (U.S.A.) law restricts this device to sale by or on the order of a physician.

Morris Plains, NJ 07950 USA
See following page for brief summary of prescribing information.

Procan® SR
(procainamide hydrochloride tablets)
SUSTAINED RELEASE
Before prescribing, please see full prescribing information.
A Brief Summary follows:

The prolonged administration of procainamide often leads to the development of a positive antinuclear antibody (ANA) test with or without symptoms of lupus erythematosus-like syndrome. If a positive ANA titer develops, the benefit/risk ratio related to continued procainamide therapy should be assessed. This may necessitate consideration of alternative antiarrhythmic therapy.

INDICATIONS: Oral procainamide is indicated in the treatment of premature ventricular contractions and ventricular tachycardia, atrial fibrillation, and paroxysmal atrial tachycardia.

CONTRAINDICATIONS: It has been suggested that procainamide be contraindicated in patients with myasthenia gravis. Hypersensitivity to the drug is an absolute contraindication; in this connection, cross-sensitivity to procaine and related drugs must be borne in mind. Procainamide should not be administered to patients with complete atrioventricular heart block. Procainamide is also contraindicated in cases of second-degree and third-degree A-V block unless an electrical pacemaker is operative.

PRECAUTIONS: During administration of the drug, evidence of untoward myocardial responses should be carefully watched for in all patients. In the presence of an abnormal myocardium, procainamide may at times produce untoward responses. In atrial fibrillation or flutter, the ventricular rate may increase suddenly as the atrial rate is slowed. Adequate digitalization reduces, but does not abolish, this danger. If myocardial damage exists, ventricular tachysystole is particularly hazardous. Correction of atrial fibrillation, with resultant forceful contractions of the atrium, may cause a dislodgement of mural thrombi and produce an embolic episode. However, it has been suggested that, in a patient who is already discharging emboli, procainamide is more likely to stop than to aggravate the process.

Attempts to adjust the heart rate in a patient who has developed ventricular tachycardia during an occlusive coronary episode should be carried out with extreme caution. Caution is also required in marked disturbances of atrioventricular conduction such as A-V block, bundle branch block, or severe digitalis intoxication, where the use of procainamide may result in additional depression of conduction and ventricular asystole or fibrillation.

Because patients with severe organic heart disease and ventricular tachycardia may also have complete heart block, which is difficult to diagnose under these circumstances, this complication should always be kept in mind when treating ventricular arrhythmias with procainamide. If the ventricular rate is significantly slowed by procainamide without attainment of regular atrioventricular conduction, the drug should be stopped and the patient re-evaluated because asystole may result under these circumstances.

In patients receiving normal dosage, but who have both liver and kidney diseases, symptoms of overdosage (principally ventricular tachycardia and severe hypotension) may occur due to drug accumulation.

Instances of a syndrome resembling lupus erythematosus have been reported in connection with maintenance procainamide therapy. The mechanism of this syndrome is uncertain. Polyarthralgia, arthritis, and pleuritic pain are common symptoms; to a lesser extent, fever, myalgia, skin lesions, pleural effusion, and pericarditis may occur. Rare cases of thrombocytopenia or Coombs-positive hemolytic anemia have been reported which may be related to this syndrome. Patients receiving procainamide for extended periods of time, or in whom symptoms suggestive of a lupus-like reaction appear, should have antinuclear antibody titers measured at regular intervals. The drug should be discontinued if there is a rising titer (antinuclear antibody) or clinical symptoms of LE appear. The LE syndrome may be reversible upon discontinuation of the drug. If discontinuation of the drug does not cause remission of the symptoms, steroid therapy may be effective. If the syndrome develops in a patient with recurrent life-threatening arrhythmias not controllable by other antiarrhythmic agents, steroid suppressive therapy may be used concomitantly with procainamide. It is recommended that tests for lupus erythematosus be carried out at regular intervals in patients receiving maintenance procainamide therapy.

ADVERSE REACTIONS: Hypotension following oral administration is rare.

Large oral doses of procainamide may sometimes produce anorexia, nausea, urticaria, and/or pruritus.

A syndrome resembling lupus erythematosus has been reported (see PRECAUTIONS). Reactions consisting of fever and chills have also been reported, including a case with fever and chills plus nausea, vomiting, abdominal pain, acute hepatomegaly, and a rise in serum glutamic oxaloacetic transaminase following single doses of the drug. Bitter taste, diarrhea, weakness, mental depression, giddiness, and psychosis with hallucinations have been reported. The possibility of such untoward effects should be borne in mind.

Hypersensitivity reactions, such as angioneurotic edema and maculopapular rash have also occurred.

Agranulocytosis has occasionally followed the repeated use of the drug, and deaths have occurred. Therefore, routine blood counts are advisable during maintenance procainamide therapy. The patient should be instructed to report any soreness of the mouth, throat, or gums, unexplained fever, or any symptoms of upper respiratory tract infection. If any of these should occur, and leukocyte counts indicate cellular depression, procainamide therapy should be discontinued and appropriate treatment should be instituted immediately.

DOSAGE AND ADMINISTRATION: Procan SR (procainamide hydrochloride tablets) are a sustained-release product form. The duration of action of procainamide hydrochloride supplied in this sustained-release product form allows dosing at intervals of every six hours instead of the more frequent every-three-hour dosing interval required for standard preparations of oral procainamide hydrochloride. The convenient six-hour dosing schedule may encourage patient compliance.

Ventricular tachycardia—Treatment with standard procainamide hydrochloride is recommended until the tachycardia is interrupted or the limit of tolerance is reached. Maintenance may then be continued with Procan SR.

The suggested dosage is as follows: An initial dose of 1 g of standard procainamide hydrochloride followed thereafter by a total daily dosage of 50 mg/kg of body weight given at three-hour intervals. The suggested oral dosage for premature ventricular contractions is 50 mg/kg of body weight daily given in divided doses at three-hour intervals.

The suggested maintenance dosage of Procan SR is 50 mg/kg of body weight daily given in divided doses at six-hour intervals.

Although the dosage for each patient must be determined on an individual basis, the following may be used as a guide for providing the total daily dosage: patients weighing less than 55 kg (120 lb), 0.5 g every six hours; patients weighing between 55 and 91 kg (120 and 200 lb), 0.75 g every six hours; and patients weighing over 91 kg (200 lb), 1 g every six hours.

Atrial fibrillation and paroxysmal atrial tachycardia—Treatment with standard procainamide hydrochloride is recommended until the arrhythmia is interrupted or the limit of tolerance is reached. Maintenance may then be continued with Procan SR.

The suggested dosage is as follows: An initial dose of 1.25 g of standard procainamide hydrochloride may be followed in one hour by 0.75 g if there have been no electrocardiographic changes. Standard procainamide hydrochloride may then be given at a dosage of 0.5 g to 1 g every two hours until interruption of the arrhythmia or the tolerance limit is reached.

The suggested maintenance dosage for Procan SR is 1 g every six hours.

If procainamide therapy is continued for appreciable periods, electrocardiograms should be made occasionally to determine the need for the drug.

HOW SUPPLIED: N 0071-0202 Procan SR 250 mg. Each sustained-release tablet contains 250 mg procainamide hydrochloride. Available in bottles of 100 tablets and in unit-dose packages of 100 (10 strips of 10 tablets each).

N 0071-0204 Procan SR 500 mg. Each sustained-release, scored tablet contains 500 mg procainamide hydrochloride. Available in bottles of 100 tablets and in unit-dose packages of 100 (10 strips of 10 tablets each).

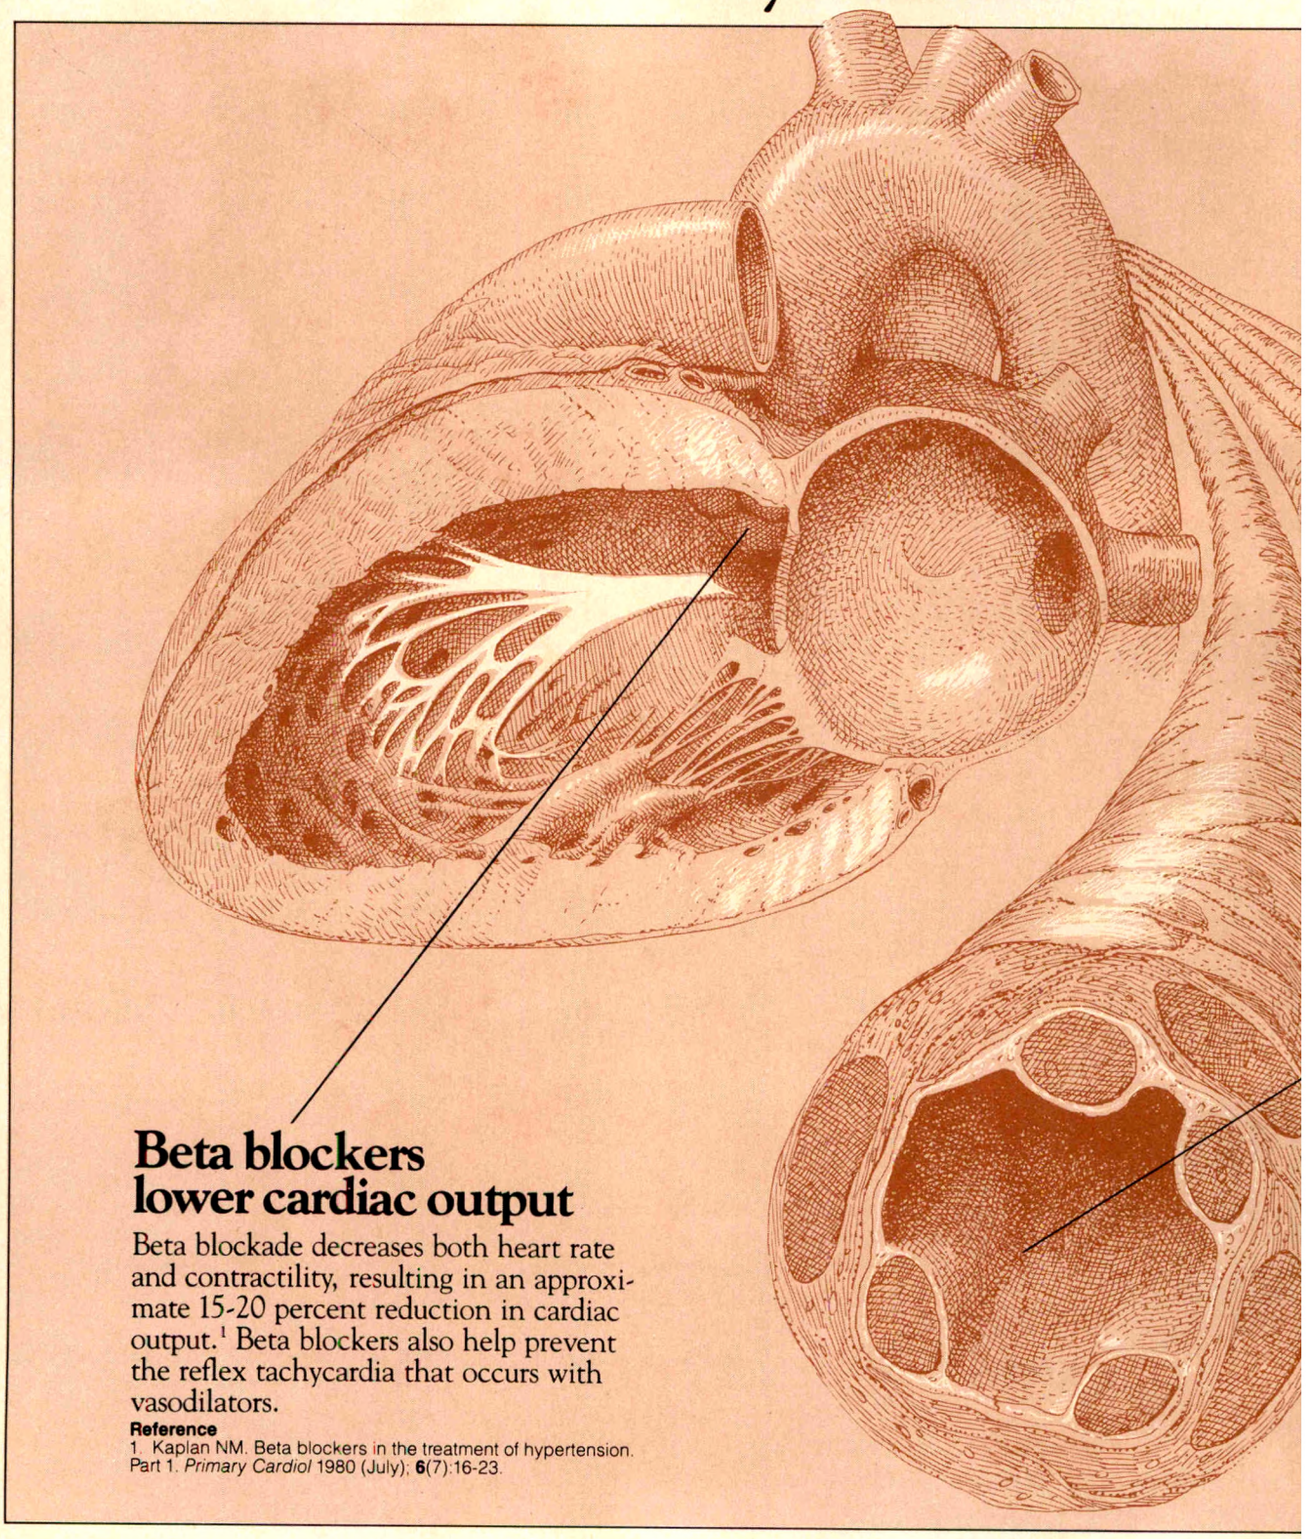
After a diuretic...

Apresoline
hydralazine



Beta blockers lower cardiac output

Beta blockade decreases both heart rate and contractility, resulting in an approximate 15-20 percent reduction in cardiac output.[1] Beta blockers also help prevent the reflex tachycardia that occurs with vasodilators.

Please turn page for brief prescribing information.

antihypertensive therapy

Apresoline® hydrochloride
hydralazine hydrochloride USP
TABLETS

INDICATIONS
Essential hypertension, alone or as an adjunct.

CONTRAINDICATIONS
Hypersensitivity to hydralazine; coronary artery disease; and mitral valvular rheumatic heart disease.

WARNINGS
Hydralazine may produce in a few patients a clinical picture simulating systemic lupus erythematosus. In such patients hydralazine should be discontinued unless the benefit-to-risk determination requires continued antihypertensive therapy with this drug. Symptoms and signs usually regress when the drug is discontinued but residua have been detected many years later. Long-term treatment with steroids may be necessary. Complete blood counts, L.E. cell preparations, and antinuclear antibody titer determinations are indicated before and periodically during prolonged therapy with hydralazine even though the patient is asymptomatic. These studies are also indicated if the patient develops arthralgia, fever, chest pain, continued malaise or other unexplained signs or symptoms. A positive antinuclear antibody titer and/or positive L.E. cell reaction requires that the physician carefully weigh the implications of the test results against the benefits to be derived from antihypertensive therapy with hydralazine.
Use MAO inhibitors with caution in patients receiving hydralazine.
When other potent parenteral antihypertensive drugs, such as diazoxide, are used in combination with hydralazine, patients should be continuously observed for several hours for any excessive fall in blood pressure. Profound hypotensive episodes may occur when diazoxide injection and Apresoline (hydralazine hydrochloride) are used concomitantly.

Usage in Pregnancy
Animal studies indicate that hydralazine is teratogenic in mice, possibly in rabbits, and not in rats. Teratogenic effects observed were cleft palate and malformations of facial and cranial bones. Although clinical experience does not include any positive evidence of adverse effects on the human fetus, hydralazine should not be used during pregnancy unless the expected benefit clearly justifies the potential risk to the fetus.

PRECAUTIONS
Myocardial stimulation produced by Apresoline can cause anginal attacks and ECG changes of myocardial ischemia. The drug has been implicated in the production of myocardial infarction. It must, therefore, be used with caution in patients with suspected coronary artery disease.
The "hyperdynamic" circulation caused by Apresoline may accentuate specific cardiovascular inadequacies. An example is that Apresoline may increase pulmonary artery pressure in patients with mitral valvular disease. The drug may reduce the pressor responses to epinephrine.
Postural hypotension may result from Apresoline, but is less common than with ganglionic blocking agents. Use with caution in patients with cerebral vascular accidents.
In hypertensive patients with normal kidneys who are treated with Apresoline, there is evidence of increased renal blood flow and a maintenance of glomerular filtration rate. In some instances improved renal function has been noted where control values were below normal prior to Apresoline administration. However, as with any antihypertensive agent, Apresoline should be used with caution in patients with advanced renal damage.
Peripheral neuritis, evidenced by paresthesias, numbness, and tingling, has been observed. Published evidence suggests an antipyridoxine effect and the addition of pyridoxine to the regimen if symptoms develop.
Blood dyscrasias, consisting of reduction in hemoglobin and red cell count, leukopenia, agranulocytosis, and purpura, have been reported. If such abnormalities develop, discontinue therapy. Periodic blood counts are advised during prolonged therapy.
The Apresoline tablets (10 and 100 mg) contain FD&C Yellow No. 5 (tartrazine) which may cause allergic-type reactions (including bronchial asthma) in certain susceptible individuals. Although the overall incidence of FD&C Yellow No. 5 (tartrazine) sensitivity in the general population is low, it is frequently seen in patients who also have aspirin hypersensitivity.

ADVERSE REACTIONS
Adverse reactions with Apresoline are usually reversible when dosage is reduced. However, in some cases it may be necessary to discontinue the drug.
Common: Headache; palpitations; anorexia; nausea; vomiting; diarrhea; tachycardia; angina pectoris.
Less frequent: Nasal congestion; flushing ; lacrimation; conjunctivitis; peripheral neuritis, evidenced by paresthesias, numbness, and tingling; edema; dizziness; tremors; muscle cramps; psychotic reactions characterized by depression, disorientation, or anxiety; hypersensitivity (including rash, urticaria, pruritus, fever, chills, arthralgia, eosinophilia, and, rarely, hepatitis); constipation; difficulty in micturition; dyspnea; paralytic ileus; lymphadenopathy; splenomegaly; blood dyscrasias, consisting of reduction in hemoglobin and red cell count, leukopenia, agranulocytosis, and purpura; hypotension; paradoxical pressor response.

DOSAGE AND ADMINISTRATION
Initiate therapy in gradually increasing dosages; adjust according to individual response. Start with 10 mg 4 times daily for the first 2 to 4 days, increase to 25 mg 4 times daily for balance of first week. For second and subsequent weeks, increase dosage to 50 mg 4 times daily. For maintenance, adjust dosage to lowest effective levels.
The incidence of toxic reactions, particularly the L.E. cell syndrome, is high in the group of patients receiving large doses of Apresoline.
In a few resistant patients, up to 300 mg Apresoline daily may be required for a significant antihypertensive effect. In such cases, a lower dosage of Apresoline combined with a thiazide, reserpine, or both may be considered. However, when combining therapy, individual titration is essential to insure the lowest possible therapeutic dose of each drug.

Congestive Heart Failure
Mechanisms, Evaluation and Treatment
Dean T. Mason, M.D.

This rare treatment of such a multifaceted subject provides an unusual opportunity for the busy clinician to add to his knowledge in a minimum amount of time. Any area of immediate interest can be rapidly located and as much data as needed can be quickly extracted. The concentration on improved clinical management will be appreciated by every internist, cardiologist, generalist, and any professional involved in cardiovascular medicine.

Dean Mason, President of the American College of Cardiology, has organized this monograph within the three areas relevant to an understanding of congestive heart failure: *mechanisms, evaluation* and *treatment*. Fifty-six recognized authorities have been assembled by Dr. Mason, each contributing their expertise to make this book the foremost text covering the highly important and common disorders of abnormal heart function.

This presentation of recent advances in basic research and clinical progress has been highly acclaimed for its major contribution to the improvement of patient care. We invite you to see if you don't agree. Order and take 30 days to look over the book. If you're not totally satisfied, return it.

About the author . . . Dean T. Mason, M.D.

Professor of Medicine, Professor Physiology, Chief of Cardiovascular Medicine, University of California, School of Medicine, Davis.

President, American College of Cardiology; President, Western Society for Clinical Research.

Member of the American Board of Internal Medicine Cardiovascular Diseases.

Has authored more than 400 original articles on cardiovascular science and clinical cardiology.

Serves on the editorial boards of The American Journal of Cardiology, The Journal of Clinical Investigation, Circulation, Chest, Clinical Pharmacology and Therapeutics, Catheterization and Cardiovascular Diagnosis, and Heart and Lung.

Recipient of Experimental Therapeutics Award in 1973 from the American Society of Pharmacology and Experimental Therapeutics, the Research Awards in 1965 from the American Therapeutic Society, and the Theodore and Susan B. Cummings Humanitarian Awards in 1972, 1973, and 1975 from the U.S. State Department and the American College of Cardiology.

Comparison of Hemodynamic Actions of Pirbuterol and Dobutamine on Cardiac Function in Severe Congestive Heart Failure

NAJAM A. AWAN, MD, FACC
KATHLEEN E. NEEDHAM, BS
MARK K. EVENSON, BS
DEAN T. MASON, MD, FACC

Davis and Sacramento, California

There is considerable interest in the development of beneficial oral inotropic agents for sustained ambulatory management of patients with severe chronic congestive heart failure. Therefore, the hemodynamic actions of the oral beta adrenergic receptor agonist pirbuterol and of intravenous dobutamine were compared in nine patients with severe heart failure. Both agents produced similar effects on ventricular pump function: The cardiac index was markedly increased from 1.8 to 2.6 liters/min per m^2 ($p < 0.005$) by dobutamine and from 1.8 to 2.9 liters/min per m^2 ($p < 0.001$) by pirbuterol; stroke index was increased from 24 to 32 ml/beat per m^2 ($p < 0.02$) by dobutamine and from 23 to 35 ml/beat per m^2 ($p < 0.001$) by pirbuterol; the stroke work index was increased from 19 to 27 g-m/m^2 ($p < 0.005$) by dobutamine and from 20 to 28 g-m/m^2 ($p < 0.005$) by pirbuterol. However, although dobutamine did not change mean blood pressure or left ventricular filling pressure ($p > 0.05$), pirbuterol modestly decreased mean blood pressure from 83 to 75 mm Hg ($p < 0.02$) and moderately decreased left ventricular filling pressure from 23 to 18 mm Hg ($p < 0.005$). Dobutamine reduced total systemic vascular resistance 22 percent from 2,049 to 1,582 dynes s cm^{-5} ($p < 0.001$), whereas pirbuterol reduced this index 42 percent ($p < 0.05$ versus dobutamine) from 2,068 to 1,150 dynes s cm^{-5}. Neither agent altered heart rate or the heart rate-systolic blood pressure product ($p > 0.05$).

Thus, oral pirbuterol has dobutamine-like beneficial hemodynamic effects on left ventricular pump function but causes a greater decrease in total systemic vascular resistance consistent with the combined inotropic and peripheral vasodilator actions of this oral beta adrenergic receptor agonist. These salutary hemodynamic responses suggest that oral pirbuterol may be useful for the prolonged treatment of severe chronic congestive heart failure.

The recent availability of potent oral vasodilators[1–4] has greatly improved ambulatory therapy of severe chronic congestive heart failure. Thereby the incorporation of systemic vasodilators into the conventional therapeutic regimens of digitalis and diuretic drugs[1–4] results in highly beneficial augmentation of cardiac pump function while ventricular preload is simultaneously decreased.[2,4–6] However, although cardiac contractility is well recognized as a fundamental regulator of cardiac pump performance,[7] the use of digitalis in the setting of severe congestive heart failure is accompanied by only modest augmentation of this major determinant of ventricular function.[7] Thus, there is considerable continuing interest in the development of safe and effective oral inotropic agents, used alone or in combination with potent systemic vasodilators, for sustained enhancement of the performance of the failing heart. Accordingly, we evaluated the hemodynamic effects of the new oral beta adrenergic receptor agonist pirbuterol on cardiac function, and compared the actions of this agent with those of intravenous dobutamine in patients with severe chronic congestive heart failure.

From the Section of Cardiovascular Medicine, Departments of Medicine and Physiology, University of California at Davis School of Medicine and Sacramento Medical Center, Davis and Sacramento, California. This study was supported in part by Program Project Grant HL-14780 from the National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, Maryland; and California Chapters of the American Heart Association, Dallas, Texas. Methods

Study patients (Table I): Nine patients (seven men and two women, mean age 59.5 years) with severe chronic congestive heart failure constituted the study group. The cause of chronic left ventricular dysfunction was ischemic heart disease with previous myocardial infarction (3 or more months earlier) documented clinically, electrocardiographically and angiographically in all patients. Significant valvular heart disease was carefully excluded in all. All patients had severe congestive heart failure despite administration of maximal doses of digoxin and diuretics, the mean left ventricular ejection fraction being 0.20. To maintain a stable clinical and hemodynamic state during the study, the usual doses of the daily medications were administered in the evenings throughout the investigation.

Cardiac catheterization: All nine patients underwent right heart catheterization with placement of the balloon-tipped thermodilution Swan-Ganz catheter in the pulmonary artery for assessment of cardiac performance. In each of these patients intraarterial blood pressure, pulmonary arterial pressures and triplicate thermodilution cardiac outputs were measured. Pulmonary arterial diastolic pressure was confirmed to be identical to pulmonary wedge pressure and was thereafter used to measure left ventricular filling pressure (LVFP). The following variables of cardiac performance were calculated: total systemic vascular resistance (TSVR, dynes s cm^{-5}) from [(MBP − RA) × 80]/CO, where MBP is mean blood pressure, RA is mean right atrial pressure and 80 is the conversion factor for converting units of resistance into dynes; stroke work index (SWI, g-m/m^2) from (MBP − LVFP) × SI × 0.0136, where SI is stroke index (ml/beat per m^2); and double product (mm Hg/min) from SBP × HR, where SBP is systolic blood pressure (mm Hg) and HR is heart rate (beats/min). Hemodynamic stability was confirmed in each patient by obtaining control measurements at 30 minutes and immediately before drug administration.

Drug administration: The study design consisted of sequential but randomized administration of a single dose of oral pirbuterol (0.4 mg/kg) or intravenous dobutamine infusion (maximal dose 20 μg/kg per min) titrated individually (mean dose [± standard error of the mean] 11 ± 3 μg/kg per min) to obtain optimal cardiac function (cardiac output 20 percent or greater with ± 5 beats/min change in heart rate). Thereby five patients received dobutamine as the initial drug (Group I) and four patients received pirbuterol first (Group II). Patients in Group I received pirbuterol at least 4 hours after dobutamine infusion when the basal hemodynamic state was reestablished after administration of dobutamine. Patients in Group II received dobutamine 36 to 48 hours after evaluation of responses to oral pirbuterol. The peak effects of the oral agent (1 to 2 hours after administration of pirbuterol) were then compared with the optimal effects of intravenous dobutamine.

Statistical analysis: Statistical data were analyzed using Student's *t* test for paired data and analysis of variance.

Results

Heart rate and blood pressure (Fig. 1): Control hemodynamic variables before administration of dobutamine were similar ($p > 0.05$) to the prepirbuterol values. The control heart rate of 79 ± 5 beats/min was not changed ($p > 0.05$) by intravenous dobutamine or oral pirbuterol. Mean systemic blood pressure was unaltered by dobutamine (control 77 ± 5, dobutamine 80 ± 6 mm Hg, $p > 0.05$), while oral pirbuterol caused a modest decrease in this variable from 83 ± 5 to 75 ± 4 mm Hg ($p < 0.02$).

Left ventricular filling pressure (Fig. 2): Although the average left ventricular filling pressure decreased during dobutamine infusion from 23 ± 3 to 19 ± 3 mm Hg, this change was not statistically significant ($p > 0.05$) because of the marked individual differences in the response of this variable in our patients. However, the abnormally elevated left ventricular filling pressure was modestly reduced by pirbuterol from 23 ± 3 to 18 ± 3 mm Hg ($p < 0.005$), and this variable decreased in most of the patients. Nevertheless, the percent decrease in left ventricular filling pressure of 24 ± 7 percent after pirbuterol did not differ significantly ($p > 0.05$) from the 18 ± 6 percent decrease produced by dobutamine.

Cardiac output (Fig. 3 and 4): Both pirbuterol and dobutamine markedly increased cardiac pump performance. Dobutamine increased the low control cardiac index of 1.8 ± 0.2 to 2.6 ± 0.3 liters/min per m^2 ($p < 0.005$), whereas oral pirbuterol increased this index from 1.8 ± 0.2 to 2.9 ± 0.3 liters/min per m^2 ($p < 0.001$). All patients given intravenous dobutamine and oral pirbuterol had an increase in cardiac index. Further, the percent increase in cardiac index was similar after pir-

7	64	Ant and Inf MI	III	0.21	Dig, Fur 200, Tri 100
8	64	Ant and Inf MI	III	0.17	Dig, Fur 320
9	60	Ant MI	III	0.12	Dig, Fur 320

Ant = anterior; Dig = digoxin, 0.25 mg; EF = left ventricular ejection fraction; Fur = furosemide; Inf = inferior; MI = old myocardial infarction; NYHA = New York Heart Association functional class[8]; Tri = triamterene.

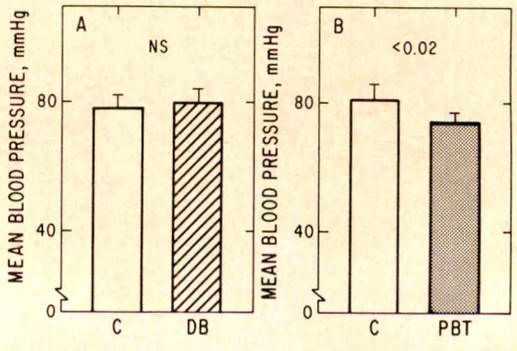

FIGURE 1. Effects of intravenous dobutamine (DB) (**panel A**) and oral pirbuterol (PBT) (**panel B**) on systemic blood pressure (mean ± standard error of the mean). C = control; NS = not significant.

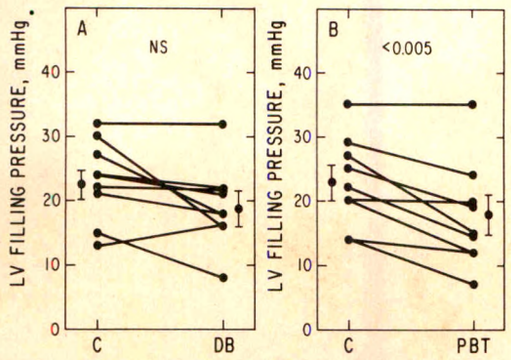

FIGURE 2. Effects of dobutamine (DB) (**panel A**) and pirbuterol (PBT) (**panel B**) on left ventricular (LV) filling pressure. C = control; NS = not significant.

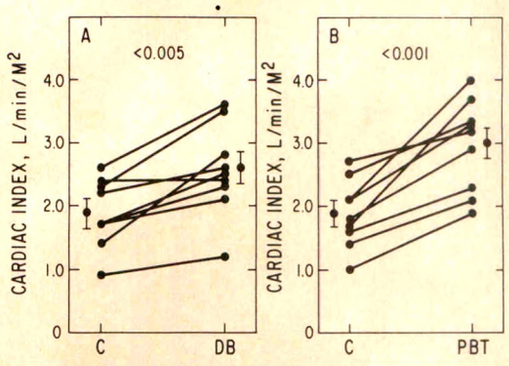

FIGURE 4. Peak effects of dobutamine (DB) (**panel A**) and pirbuterol (PBT) (**panel B**) on cardiac index. C = control.

buterol (38 ± 4 percent) and dobutamine (31 ± 4 percent) ($p > 0.05$). Concomitantly, because the heart rate remained unchanged, the stroke volume index was equally enhanced by both agents. The control stroke index of 24 ± 3 was increased to 32 ± 4 ml/beat per m^2 ($p < 0.02$) by dobutamine and from 23 ± 2 to 35 ± 4 ml/beat per m^2 ($p < 0.001$) by oral pirbuterol.

Stroke work index and systemic vascular resistance (Fig. 5): The stroke work index increased ($p < 0.005$) with both drugs (control 19 ± 5, dobutamine 27 ± 6; control 20 ± 3, pirbuterol 28 ± 6 g-m/m^2). Moreover, total systemic vascular resistance decreased ($p < 0.001$) with both agents (control 2,049 ± 341, dobutamine 1,582 ± 341; control 2,068 ± 291, pirbuterol 1,150 ± 170 dynes s cm^{-5}). However, despite similar effects on preload and cardiac pump function, the 42 ± 4 percent reduction in this variable produced by pirbuterol exceeded the 22 ± 3 percent decrease produced by intravenous administration of dobutamine ($p < 0.05$).

The control double product (heart rate × systolic blood pressure) of 10,040 mm Hg/min was unchanged ($p > 0.05$) by both agents. Moreover, neither drug caused left ventricular ischemia or increased ventricular arrhythmia.

Discussion

Similarity of pirbuterol and dobutamine salutary effects: This investigation clearly demonstrates that oral pirbuterol produces a marked increase in cardiac pump function in patients with severe congestive heart failure. The unique feature of this study is that it reveals that the major salutary actions of pirbuterol on left ventricular function are similar to the beneficial effects of the well recognized intravenous inotropic agent dobutamine. Thus, the substantial increase in cardiac index (Fig. 4B) and the moderate decrease in left ventricular filling pressure (Fig. 2B) caused by oral pirbuterol were similar to the beneficial augmentation in these variables (Fig. 2A and 4A) during dobutamine infusion. Similarly, stroke index and stroke work index were equally increased by the two drugs.

Differences between pirbuterol and dobutamine: Important differences in the extent of hemodynamic effects on some variables were also perceived. Thus, a moderate decrease in mean systemic blood pressure occurred with oral pirbuterol (Fig. 1B). Further, although the average decreases in elevated left ventricular filling pressure produced by the two drugs were equal (Fig. 3B), pirbuterol consistently produced a modest

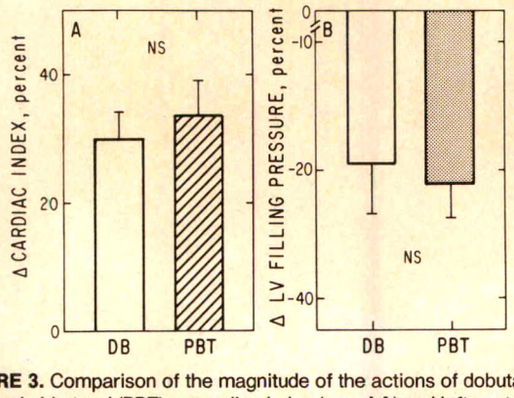

FIGURE 3. Comparison of the magnitude of the actions of dobutamine (DB) and pirbuterol (PBT) on cardiac index (**panel A**) and left ventricular (LV) filling pressure (**panel B**). Δ = change; NS = not significant.

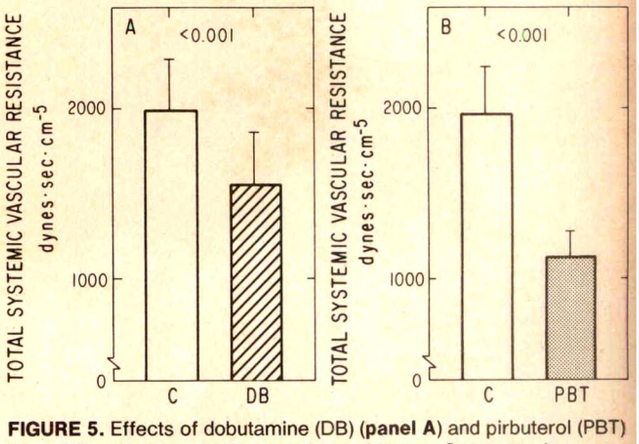

FIGURE 5. Effects of dobutamine (DB) (**panel A**) and pirbuterol (PBT) (**panel B**) on total systemic vascular resistance. C = control.

decrease in this variable (Fig. 2B), whereas the dobutamine responses were more variable (Fig. 2A). Additionally, although pirbuterol resulted in a beneficial improvement in left ventricular pump output similar to that produced by dobutamine, with pirbuterol the improvement was accompanied by a greater decrease in total systemic vascular resistance (Fig. 5).

Mechanisms of action: These observations of similar pump actions but disparate peripheral vascular actions of the two agents may be importantly related to the mechanisms of action of the drugs. Dobutamine produces predominantly $beta_1$ adrenergic receptor agonist effects,[7–10] thereby augmenting myocardial contractility[7] and cardiac pump output.[9–11] In contrast, oral pirbuterol is more nonselective,[12] particularly in the larger doses used in our patients with heart failure, leading to stimulation of $beta_1$ as well as $beta_2$ adrenergic receptors.[13,14] Therefore, the beneficial effects of pirbuterol are probably caused by combined central inotropic and peripheral vasodilator actions of this agent. This concept of simultaneous vasorelaxant and inotropic effects of the oral agent are consistent with our results. Accordingly, despite equal effects of the two drugs on left ventricular pump function, pirbuterol produced a greater reduction in total systemic vascular resistance than did dobutamine (Fig. 5). Similarly, although the latter drug did not change systemic blood pressure, this variable decreased modestly after pirbuterol ingestion (Fig. 1). Nevertheless, the precise extent of the contribution of these two actions, inotropic and vasodilator, to the pharmacodynamic profile of this oral beta agonist are difficult to quantify, and it remains possible that vasodilator actions of pirbuterol may predominate. Indeed, a similar hemodynamic response is well known with some pure arteriolar relaxing agents.[1] Despite uncertainty concerning the exact mechanism of action of the drug, our results demonstrate that oral pirbuterol provides dobutamine-like beneficial hemodynamic effects indicating a useful potential for outpatient therapy of severe congestive heart failure with this agent.

Mechanism of reduced left ventricular preload: Concerning the possible mechanisms of the reduced left ventricular preload noted in this study, a decrease in end-systolic volume associated with augmented contractility and enhanced left ventricular ejection fraction is known to decrease left ventricular filling pressure.[15] Thus, the reduction in this variable noted in some patients during infusion of dobutamine (Fig. 2A) is probably related to the aforementioned mechanism of improved ejection fraction and elevated cardiac output. However, a decrease in cardiac preload was more consistently noted after pirbuterol administration (Fig. 2B) despite similar enhancement of the cardiac output as dobutamine. Further, we have previously shown[14] that oral pirbuterol causes a decrease in venous tone, thereby reducing cardiac preload. Thus, it is probable that the pirbuterol-effected fall in left ventricular filling pressure is the result of augmented myocardial contractility, decreasing end-systolic volume, combined with the beneficial venodilator actions of the drug. Regardless of the mechanism of this helpful decrease in elevated left ventricular filling pressure, the useful preload-lowering effect of pirbuterol is usually of modest magnitude. Therefore, during ambulatory therapy of severe heart failure it may sometimes be necessary to combine pirbuterol with an effective venodilator agent to provide salutary improvement in congestive symptoms.

Therapeutic implications: Although these salutary hemodynamic actions of oral pirbuterol are encouraging, the determination of precise therapeutic usefulness of this agent in the prolonged management of patients with severe chronic congestive heart failure must await further trials. Initial experience with this agent at our institutions did not demonstrate precipitation of increased ventricular arrhythmia or exacerbation of myocardial ischemia. Accordingly, if further controlled evaluation confirms continued efficacy and safety of this agent, the incorporation of oral pirbuterol into the pharmacologic approach to the management of severe chronic congestive heart failure may represent a significant therapeutic advance.

Hemodynamic Effects of Intravenous Prenalterol in Severe Heart Failure

PHILIP C. KIRLIN, MD*
BERTRAM PITT, MD, FACC

Ann Arbor, Michigan

Nine patients with chronic severe low output heart failure (radionuclide left ventricular ejection fraction 17 ± 5 percent [mean ± standard deviation], left ventricular filling pressure 26 ± 6 mm Hg, cardiac index 1.9 ± 0.4 liters/min per m^2, left ventricular stroke work index 18 ± 6 g-m/m^2) from various causes were treated with intravenous prenalterol (a new catecholamine-like inotropic agent) in doses of 1, 4 and 8 mg. Significant hemodynamic improvement occurred as measured by increased left ventricular ejection fraction (to 26 ± 4 percent), decreased left ventricular filling pressure (to 21 ± 8 mm Hg) and increased cardiac index (to 2.4 ± 0.6 liters/min per m^2) and left ventricular stroke work index (to 25 ± 8 g-m/m^2). Significant increases in heart rate (from 87 ± 18 to 91 ± 18 beats/min) and mean systemic arterial pressure (from 87 ± 8 to 92 ± 7 mm Hg) also occurred. Peak hemodynamic response occurred at various doses. Significant adverse effects associated with prenalterol consisted of increased ventricular ectopic beats in two patients and asymptomatic ventricular tachycardia in two patients. Thus, intravenous prenalterol produces hemodynamic improvement in patients with a chronic severe low output state but may be associated with increased ventricular ectopic activity.

Prenalterol (levorotatory form of 1-isopropylamino-3-[p-hydroxyphenoxy]-2-propanol hydrochloride) is a new catecholamine-like cardiac inotropic agent which has been shown in animal[1,2] and human[3–9] studies to possess relatively selective $beta_1$ adrenergic stimulating properties, resulting in a positive inotropic response with acceptable chronotropic and vasoactive properties. Because it is effective both orally and parenterally, it has been proposed for use in the therapy of both acute and chronic heart failure, including potential use as an adjunct or substitute for cardiac glycoside therapy in selected patients. The current study was undertaken to provide an evaluation of the hemodynamic effects of intravenously administered prenalterol in patients with severe low output heart failure.

Methods

Study patients: Nine patients (mean age 59 ± 7 years) with chronic severe symptomatic heart failure (New York Heart Association[10] functional class II to IV; left ventricular filling pressure, determined from mean pulmonary arterial wedge pressure, greater than or equal to 16 mm Hg; and left ventricular ejection fraction less than or equal to 30 percent) were included. Seven of the nine patients were in the cardiac intensive care unit for management of heart failure at the time of investigation. Six patients had ischemic heart disease, two had idiopathic failure and one had alcoholic cardiomyopathy. The clinical diagnosis of severe left ventricular dysfunction was substantiated by cardiac catheterization with selective coronary angiography in seven patients, and in the remaining two patients it was supported by M mode echocardiography.

Before study, a complete history was obtained and physical examination was performed with emphasis placed on New York Heart Association functional class and signs of heart failure. Five patients were chronically digitalized with oral

digoxin at the time of investigation in doses ranging from 0.125 to 0.25 mg daily. Serum digoxin levels in digitalized patients obtained within 1 to 6 days of prenalterol administration ranged from 0.26 to 1.05 mg/ml (mean 0.74). No patient had clinical evidence of digitalis toxicity. All patients required chronic diuretic therapy. Prior antiarrhythmic therapy in two patients (disopyramide, 100 mg orally four times daily, in Patient 8 and quinidine sulfate, 200 mg orally four times daily, in Patient 9), was continued throughout the study. Vasodilators were withheld for 24 hours. Digitalis and diuretic agents were administered at least 6 hours before and antiarrhythmic medications were withheld during administration of the investigational agent. Patients with unstable angina, acute myocardial infarction within 3 months or hypertrophic cardiomyopathy were excluded. The investigative protocol was approved by the Human Use Committee of the University of Michigan Medical Center, and written informed consent was obtained from each patient before study.

Hemodynamic measurements: All patients were studied in the postabsorptive state after placement of a flow-directed pulmonary arterial thermodilution catheter. Systemic arterial pressure was monitored by radial or brachial arterial catheter (seven patients) or sphygmomanometer (two patients). Heart rate was determined from the electrocardiogram. Other hemodynamic variables were determined as follows: Cardiac output was determined in eight patients by thermodilution technique (10 cc of iced 5 percent dextrose in water injected by pneumatic pump) and in one patient by indocyanine green using a Lexington cardiac output computer. The mean of triplicate thermodilution or duplicate green dye values was determined at each interval. Pulmonary arterial systolic and diastolic pressures and mean pulmonary arterial, mean pulmonary arterial wedge and mean right atrial pressures were obtained directly from the flotation catheter connected to Statham P23DB pressure transducers recorded on an Electronics for Medicine VR12 recorder. Derived hemodynamic variables were obtained from standard formulas. Left ventricular filling pressure was determined from mean pulmonary arterial wedge pressure.

Radionuclide studies: Left ventricular ejection fraction was determined by equilibrium radionuclide gated cardiac blood pool imaging using 10 to 20 mCi of technetium-99m for in vivo labeling of circulating red blood cells. A gamma camera oriented in the modified left anterior oblique position was used for cardiac blood pool imaging. Technically satisfactory radionuclide studies were obtained in eight of the nine patients.

Other laboratory studies: Continuous 24 hour electrocardiographic (Holter) monitoring was obtained on the day of the study for arrhythmia analysis. A minimum of 8 hours of electrocardiographic monitoring was recorded before administration of the investigational drug. Chest roentgenography, 12 lead electrocardiography, complete blood count, platelet count, reticulocyte count, prothrombin time, partial thromboplastin time, urine analysis and determination of SMA 12 blood chemistry values, electrolytes and cardiac enzymes (creatine kinase with isoenzyme pattern, lactic dehydrogenase with isoenzyme pattern and serum glutamic oxaloacetic transaminase analysis) were performed before administration of prenalterol. Analysis of all laboratory data except the chest roentgenogram was repeated after drug administration and compared with pretreatment values.

Prenalterol administration: After two control measurements in the resting state, intravenous prenalterol was administered through a peripheral intravenous line in doses of 1, 4 and 8 mg at 30 minute intervals. Each dose was given over 5 minutes by infusion pump, and hemodynamic measurements were performed over 5 minutes beginning 10 and 25 minutes after 1 and 4 mg doses and 10, 25 and 55 minutes after 8 mg doses. The mean of two baseline control values was used for comparison with values after drug administration.

Statistical analysis: All values were expressed as mean ± standard deviation. Statistical analysis was performed using the paired *t* test. A probability (p) value of less than or equal to 0.05 was considered statistically significant.

Results

Severe chronic impairment of left ventricular function was present in all patients. Eight of the nine patients had had symptoms of heart failure for at least 1 year and one patient had had such symptoms for 4 months. Six patients were in New York Heart Association functional class IV, two were in class III and one patient was in class II. Eight of the nine patients had a left ventricular third heart sound (S_3) at the time of study, and seven had received venous or arterial vasodilator therapy for refractory heart failure.

Hemodynamic effects of prenalterol: Hemodynamic data revealed significant improvement in cardiac index and left ventricular stroke work index and ejection fraction associated with a decrease in left ventricular filling pressure (Table I, Fig. 1). Statistically significant increases in systemic and mean arterial pressures and heart rate occurred as well. Diastolic arterial pressure and systemic arteriolar resistance did not change significantly. Pulmonary vascular resistance and mean right atrial pressure decreased significantly. Increases in right ventricular stroke work index were nearly statistically significant ($p < 0.06$). No significant differences were noted among the three doses, and the peak hemodynamic effect occurred variably after the 1, 4 or 8 mg doses.

Effect on ventricular arrhythmia: No adverse hemodynamic effects were noted except for a transient asymptomatic decrease in ejection fraction, cardiac index and stroke work index in Patient 4. Electrocardiographic monitoring revealed ectopic ventricular complexes during the control period in all patients. During subsequent drug administration, two patients had an increased number of ventricular ectopic complexes, and transient unsustained asymptomatic ventricular tachycardia developed in two patients. Patient 5 had had frequent three beat ventricular tachycardia before drug administration and a prolonged (172 beat) run of ventricular tachycardia after drug administration. Prenalterol administration was discontinued in this patient and no further ventricular tachycardia was noted on subsequent 24 hour monitoring. Patient 7 manifested a nine beat ventricular tachycardia after drug administration without previous or subsequent ventricular tachycardia. Both Patients 5 and 7 received concomitant digoxin therapy at the time of study. Prenalterol therapy was discontinued in Patient 6 after administration of 4 mg because the number of ventricular ectopic complexes increased.

Adverse effects: All patients tolerated prenalterol administration without subjective complaints of angina pectoris, palpitations, worsening shortness of breath or other symptoms. No electrocardiographic signs of in-

creased ischemia were noted during drug administration. Evaluation of laboratory values after drug administration revealed no adverse effects on hematologic, hepatic or cardiac variables, including cardiac enzyme analysis.

Discussion

Recent advances in the medical management of low output heart failure include the introduction of vasodilator therapy for ventricular preload and afterload reduction as well as the introduction of the potent new parenteral inotropic agents dopamine and dobutamine. However, the only oral inotropic agents currently available for clinical use are the cardiac glycosides, which are associated with a significant incidence of toxicity, including life-threatening cardiac arrhythmias.[11] Digitalis cardiac toxicity may be enhanced by the frequent concurrent administration of potassium-depleting diuretic drugs and quinidine, which significantly increases serum digoxin levels and thereby may increase myocardial glycoside concentration to toxic levels.[12] In addition, several investigators have suggested that chronic cardiac glycoside therapy may be ineffective in some patients with heart failure, as evidenced by a return to pretreatment hemodynamic status upon withdrawal of chronic digitalis therapy.[13–16]

Because cardiac glycosides remain less than ideal agents for chronic inotropic therapy of heart failure despite 2 centuries of use, other orally effective inotropic agents are being actively investigated.

Pharmacologic features of prenalterol: The new inotropic agent prenalterol is a derivative of phenol with a chemical structure resembling the catecholamine isoproterenol. The presumed mechanism of action is stimulation of cardiac beta$_1$ adrenergic receptors, which appears to be mediated directly since reserpine-treated animals maintain an inotropic response after administration of prenalterol.[1] It is effective both parenterally and orally and has relatively selective inotropic effects with a smaller effect on heart rate and systemic arterial pressure.

Animal studies by Carlsson et al.[1] demonstrated dose-dependent increases in the rate of rise of left ventricular pressure (dP/dt) after intravenous prenalterol with fewer chronotropic and arterial vasodilating properties than isoproterenol or terbutaline. Oral administration of 5 to 20 mg of prenalterol by Knaus et al.[3] to normal volunteers resulted in shortened systolic time intervals with significant increases in heart rate and systolic arterial pressure and a transient decrease in diastolic arterial pressure. Sinus arrhythmias increased significantly with no increase in ventricular or supraventricular extrasystoles. The inotropic effects of prenalterol in normal volunteers are blocked by the selective beta$_1$ adrenergic blocking agent metoprolol.[4] Pharmacokinetic data in normal volunteers demonstrated a mean plasma half-life of 2 hours after intravenous administration of prenalterol,[4] compared with a plasma half-life of 2 minutes for dobutamine.[17] Prenalterol's electrophysiologic properties include shortened atrioventricular nodal conduction time and atrial refractory period.[18]

Clinical hemodynamic effects of prenalterol: Previous clinical investigations in patients with cardiac disease have also demonstrated beneficial hemodynamic effects. Hutton et al.[6] demonstrated increased left ventricular dP/dt after intravenous administration of prenalterol in patients with ischemic heart disease without changes in heart rate or end-diastolic volume. Prenalterol reversed the decreased heart rate, blood pressure and cardiac output and the increased preejection period after adrenergic blockade with metoprolol following acute myocardial infarction.[5] A preliminary study of oral prenalterol in patients with severe heart failure (functional classes III and IV) showed beneficial effects on left ventricular filling pressure, cardiac index, ejection fraction and exercise tolerance.[7] Hypotension induced by spinal anesthesia has been reversed by prenalterol.[19] No significant adverse effects have previously been reported after administration of prenalterol.

The possibility that prolonged administration of prenalterol may be associated with a diminished response, a phenomenon noted with other adrenergic stimulants[20] including dobutamine,[21] has not been investigated. The hemodynamic effects of prenalterol compared with other inotropic agents such as dobutamine and dopamine have not been reported.

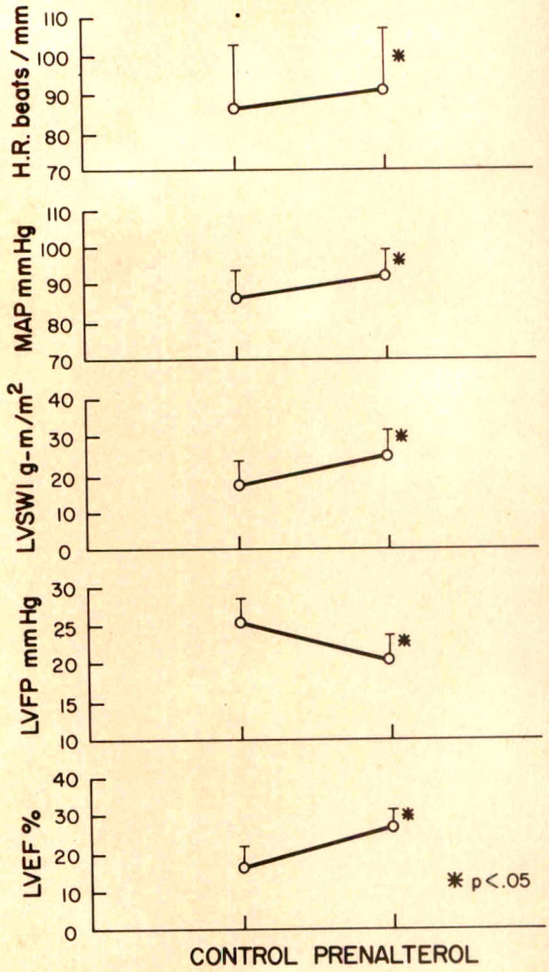

FIGURE 1. Effects of prenalterol on selected hemodynamic variables. Values are expressed as mean ± standard deviation for control state before drug administration and at peak effect. H.R. = heart rate; LVEF = left ventricular ejection fraction; LVFP = left ventricular filling pressure; LVSWI = left ventricular stroke work index; MAP = mean arterial pressure.

The present study demonstrates significant improvement in hemodynamic status after intravenous administration of prenalterol. However, our investigation differs from most previous studies in that only patients with severe low output failure are included. In our study, improved left ventricular performance is demonstrated by statistically significant increases in left ventricular ejection fraction, left ventricular stroke work index and cardiac index. Diminished left ventricular filling pressure may be due to a direct positive inotropic effect resulting in decreased left ventricular end-diastolic volume or due to left ventricular preload reduction from systemic venodilation, or both. The significant reduction in right atrial pressure in our study suggests a systemic venodilating effect. The net hemodynamic effect is a shift in the ventricular function

urve upward and to the left, as found with other inotropic agents. A statistically significant increase in heart ate after prenalterol indicates a residual chronotropic ffect, which may be mediated by stimulation of cardiac eta$_1$ adrenergic receptors affecting heart rate. The ncrease in systolic and mean arterial pressures achieved tatistical significance; however, diastolic arterial ressure did not change significantly. These findings re in agreement with those of previous studies.[4,5] A ecrease in systemic vascular resistance after administration of prenalterol suggests that the increased ystolic and mean arterial pressures are related to increased cardiac contractile force rather than arterial asoconstriction. Significant left ventricular afterload eduction, either by direct beta adrenergic arterial asodilation or by reflex withdrawal of heightened ympathetic vasoconstrictor tone, is a mechanism by hich beta adrenergic stimulants can improve left entricular performance.[22]

Inotropic effect in the presence of myocardial schemia: The decrease in abnormally elevated pulonary vascular resistance after administration of renalterol in this study is comparable with similar hanges noted with dobutamine.[22] There was considrable variation in the patients' response to prenalterol Table I). Although increases in heart rate and systemic ystolic and mean arterial pressure achieved statistical gnificance, it is unlikely that the modest nature of nese changes would be harmful in most patients. In ndividual patients, increased ischemia could result om increases in myocardial oxygen consumption (reected by an increased pressure-rate product) greater nan the increase in blood flow to ischemic tissue caused y beta$_1$ adrenergic stimulation.[23] However, no subctive or objective evidence of aggravated ischemia was resent in this study or that of Ariniego et al.,[5] who valuated prenalterol therapy after recent myocardial nfarction. Similarly, another selective inotropic agent, dobutamine, was not shown to exert an adverse effect on the size of myocardial infarction in experimental animals[24] and in patients.[25]

Prenalterol and ventricular arrhythmia: The only adverse effects found in this study were cardiac arrhythmias. Although catheter-induced arrhythmias or arrhythmias related to the underlying disease cannot be excluded, the temporal association of the arrhythmias with drug administration suggests a causal relation. Ventricular ectopic activity has been observed with other inotropic agents including the catecholamine dobutamine[26] and dopamine,[27] and these agents may have been equally arrhythmogenic in the patients included in this study. Both patients with ventricular tachycardia after administration of prenalterol in this investigation received chronic oral digoxin therapy (with serum levels in the therapeutic range) for ischemic congestive cardiomyopathy after myocardial infarction, raising the possibility that the combination of prenalterol or other adrenergic inotropic agents and digoxin may induce serious ventricular arrhythmias. Increased sympathetic activity has been associated with digitalis toxicity[28] and, conversely, beta adrenergic blockade has been found to be of value in the therapy of digitalis-induced cardiac arrhythmias.[29] Two of our five patients receiving long term oral digoxin therapy did not leave an increase in ventricular ectopic activity. However, the combination of severe ischemic heart failure and previous digoxin therapy appears to warrant particular caution in the administration of prenalterol.

Acknowledgment

We acknowledge the assistance of Steven Hewlett, the nursing staff of the Cardiac Intensive Care Unit and Jean Clare and Kathleen Worthington of the Nuclear Medicine Division, all of the University of Michigan Medical Center. AB Haessle, a division of AB Astra, kindly supplied prenalterol and provided grant support for the study.

Aprindine was administered both intravenously and orally to 25 patients with ventricular tachycardia refractory to conventional antiarrhythmic agents to test the hypothesis that the response to intravenous aprindine predicts the response to oral aprindine. Ten patients had incessant ventricular tachycardia and 15 had paroxysmal sustained inducible ventricular tachycardia.

Eleven patients (43 percent) had conversion to sinus rhythm with intravenous aprindine (nine with incessant and two with paroxysmal sustained ventricular tachycardia). Thirteen patients (all with paroxysmal sustained ventricular tachycardia) manifested slowing of the tachycardia without conversion, whereas in one patient with incessant ventricular tachycardia, the tachycardia became less frequent and nonsustained after intravenous aprindine. All 11 patients who had conversion to sinus rhythm with intravenous aprindine remained free of ventricular tachycardia during oral treatment with aprindine (at 2 weeks) and for a follow-up period of 2 to 38 months (mean 16 ± 13). Of the 14 patients who did not have conversion to sinus rhythm with intravenous aprindine, 12 had spontaneous or inducible ventricular tachycardia, or both, at evaluation 1 to 2 weeks after initiation of oral aprindine.

In conclusion, administration of intravenous aprindine to patients with ventricular tachycardia is helpful in predicting the subsequent response to oral aprindine. In addition, the pattern of ventricular tachycardia predicted the response to aprindine; patients with incessant ventricular tachycardia tended to respond, and those with paroxysmal sustained ventricular tachycardia tended not to respond.

Aprindine is an experimental antiarrhythmic agent useful for management of recurrent drug-resistant ventricular tachycardia. The drug exists for human use as both an intravenous and oral formulation. The half-life of the oral preparation varies from 13 to 50 hours,[1] often necessitating a 1 to 2 week inpatient trial before the efficacy of its oral administration can be adequately assessed. Because of this long trial period, we hypothesized that perhaps the response to intravenous aprindine might predict the response to oral aprindine. If this were the case, then patients could be preselected for oral aprindine therapy based on response to intravenous aprindine, with expectation of cure.

In the present study, we tested the hypothesis that the response to intravenous aprindine predicts the response to oral aprindine. In addition, we also made observations concerning characteristics of ventricular tachycardia that predict a successful response to this antiarrhythmic agent.

Methods

Selection of patients: Criteria for inclusion in this study were as follows: (1) the occurrence of chronic recurrent symptomatic ventricular tachycardia; (2)

From the Section of Cardiology, Department of Medicine, Abraham Lincoln School of Medicine, University of Illinois, Chicago, Illinois. This study was supported in part by Grants HL 18794, HL 23566 and Training Grant HL 17378 from the National Institutes of Health, Bethesda, Maryland, and a grant from the Eleanor B. Pillsbury Resident Trust Fund. Manuscript received July 7, 1980; revised manuscript received October 6, 1980, accepted October 9, 1980.

documentation of drug resistance to three or more antiarrhythmic drugs, (procainamide, quinidine, disopyramide or propranolol) as manifested by either the clinical occurrence of ventricular tachycardia during intravenous or oral drug trials, or both, or by the demonstration of laboratory induction of ventricular tachycardia after drug administration[2,3]; (3) the occurrence of spontaneous or induced ventricular tachycardia at a rate and duration suitable for administration of intravenous aprindine, or the occurrence of ventricular tachycardia that was too fast and too poorly tolerated to permit administration of aprindine according to the intravenous protocol (see later), but that was inducible with programmed stimulation, so that intravenous aprindine could be administered just before attempted induction of ventricular tachycardia; and (4) the testing of both intravenous and oral aprindine.

Study patients (Table I): The study group consisted of 25 patients with chronic symptomatic ventricular tachycardia. Their ages ranged from 16 to 69 years (mean 55 ± 14); 20 were male and 5 female. All except 1 patient had organic heart disease; 20 had chronic ischemic heart disease (all with remote infarction more than 3 weeks before the initial onset of ventricular tachycardia), 3 had primary myocardial disease (congestive cardiomyopathy) and 1 had hypertensive cardiovascular disease.

Characteristics of ventricular tachycardia: Patients could be categorized on the basis of the pattern of occurrence of ventricular tachycardia (Table I). Patients 1 to 15 had sporadic paroxysmal sustained ventricular tachycardia. These patients were afflicted with sustained and persistent attacks of ventricular tachycardia, necessitating conversion either electrically or with parenteral medication, or both. The frequency of occurrence of ventricular tachycardia ranged from 3 to 20 attacks/year (mean 7 ± 5). The ventricular tachycardia rates ranged from 140 to 260 beats/min (mean 188 ± 37). The QRS complex during ventricular tachycardia had a right bundle branch block pattern in 11 patients (7 patients with left and 4 with right axis deviation), and a left bundle branch block pattern in the remaining 4 patients (all with left axis deviation). Ventricular tachycardia was inducible by programmed electrical stimulation in all of these patients.

Ten patients (Patients 16 to 25) could be categorized by the presence of incessant ventricular tachycardia. In these patients, the control state (without medication) was usually characterized by persistent ventricular tachycardia, either sustained or nonsustained (episodes of ventricular tachycardia interrupted by short periods of normal sinus rhythm). The duration of the episode or episodes of incessant ventricular tachycardia before testing with intravenous aprindine ranged

CNSR = conversion to normal sinus rhythm; NSR = normal sinus rhythm; VT = ventricular tachycardia.

from 4 hours to 15 days (mean 5 ± 5 days). The rates of the tachycardia ranged from 125 to 205 beats/min (mean 160 ± 21). The QRS complex during ventricular tachycardia had a right bundle branch block pattern in four patients (two with left and two with right axis deviation) and a left bundle branch block pattern in six (four with left and two with right axis deviation).

Aprindine protocol and follow-up: In 20 patients (10 with sporadic and 10 with incessant paroxysmal sustained ventricular tachycardia), intravenous aprindine was administered during ventricular tachycardia with an infusion rate of 5 mg/min to a total dose of 200 mg over 40 minutes. In five patients (Cases 3, 7, 8, 10 and 15) with paroxysmal sustained ventricular tachycardia, the rate of ventricular tachycardia was too fast to tolerate the 40 minute infusion, so that 200 mg of aprindine was administered during sinus rhythm (5 mg/min for 40 minutes) immediately before attempted induction of ventricular tachycardia. Oral aprindine was administered in

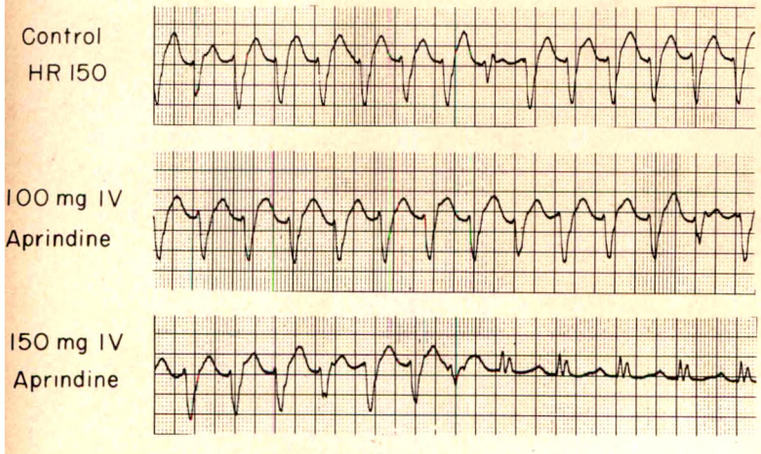

FIGURE 1. Conversion of ventricular tachycardia to normal sinus rhythm with intravenous (IV) aprindine in a patient with incessant ventricular tachycardia. HR = heart rate (beats/min).

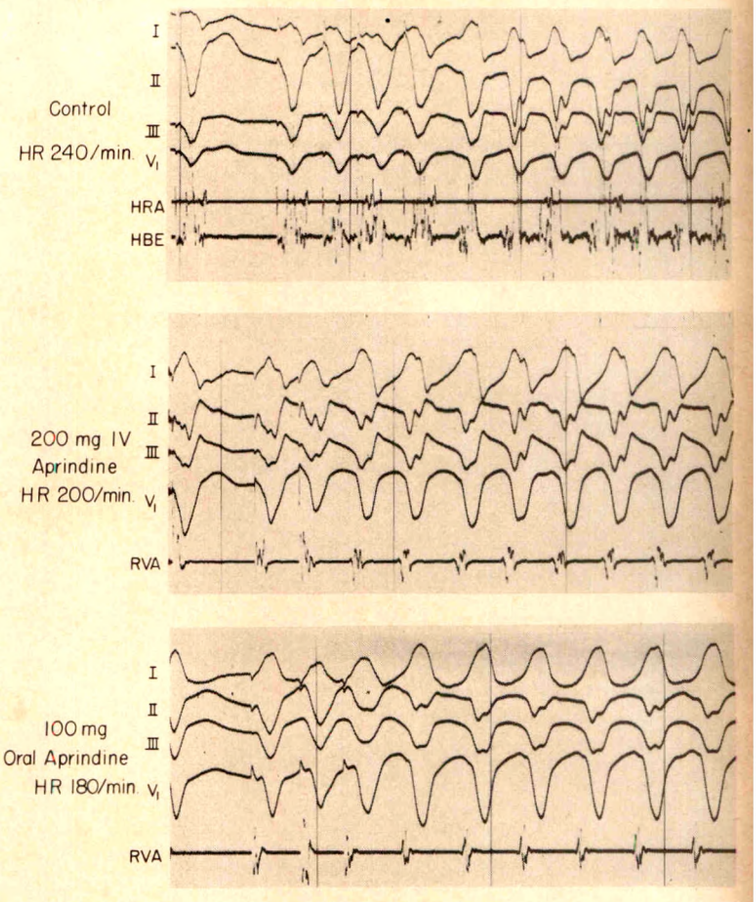

FIGURE 2. Slowing of induced ventricular tachycardia with intravenous (IV) and oral aprindine. Each panel demonstrates ventricular extra-stimulus induction of sustained ventricular tachycardia. No conversion to sinus rhythm was observed. HBE = His bundle electrogram; HR = heart rate (beats/min); HRA = high right atrium; RVA = right ventricular apex.

a daily dose of 100 to 300 mg with the dose adjusted depending on the occurrence of neurotoxicity. Inpatient monitoring was utilized during the initial oral drug trial. Outpatient follow-up study was instituted in appropriate patients in our arrhythmia clinic (see later).

Cure of ventricular tachycardia was defined by the absence of ventricular tachycardia with prolonged inpatient and outpatient monitoring in the patients with incessant ventricular tachycardia, or by inability to induce ventricular tachycardia with electrophysiologic studies as well as lack of recurrence of arrhythmia in the patients with paroxysmal sustained ventricular tachycardia. Statistical analyses were performed utilizing the chi-square test.

Results

Intravenous aprindine (Table II): Intravenous aprindine resulted in conversion to normal sinus rhythm in 11 (44 percent) of the 25 patients. Of these 11 patients, 9 (Cases 16 to 24) had incessant and 2 (Cases 13 and 14) had paroxysmal sustained ventricular tachycardia. In the latter two, aprindine was given during an induced attack in the first patient and during a spontaneous attack in the second. These 11 patients had conversion at a dose of 25 to 200 mg (mean 134 ± 58) of intravenous aprindine. In all 11 conversion of ventricular tachycardia was preceded by a slowing of ventricular rate (Fig. 1).

Intravenous aprindine failed to convert ventricular tachycardia in 14 patients (56 percent) (Cases 1 to 12, 15 and 25). Slowing of induced or spontaneous ventricular tachycardia without conversion to sinus rhythm was seen in 13 of these patients (Fig. 2). In these patients ventricular rate was slowed by 20 to 60 beats/min (mean 39 ± 12) with a resulting mean rate of ventricular tachycardia of 190 beats/min before and 151 beats/min after intravenous aprindine. In one patient (Case 25) with incessant ventricular tachycardia, the tachycardia became less incessant but did not slow.

Oral aprindine at 1 to 2 weeks (Table II): The nine patients with incessant ventricular tachycardia who had conversion to sinus rhythm with intravenous aprindine were monitored, and no recurrence of ventricular tachycardia was noted at 2 weeks. In one patient (Case 13) with paroxysmal sustained ventricular tachycardia who had conversion to sinus rhythm with intravenous aprindine, an electrophysiologic study 2 weeks after oral aprindine demonstrated inability to induce ventricular tachycardia. One patient (Case 14) was not studied at 1 to 2 weeks but was started on long-term oral aprindine therapy (see later).

The 13 patients with slowing of ventricular tachycardia without conversion to sinus rhythm after intravenous aprindine (Cases 1 to 12 and 15) were restudied

1 to 2 weeks after initiation of oral aprindine therapy. Eleven patients had inducible ventricular tachycardia (Fig. 2), whereas in two patients (Cases 1 and 2) ventricular tachycardia was no longer inducible. The patient (Case 25) with incessant ventricular tachycardia (not responding to intravenous aprindine) had spontaneous and inducible ventricular tachycardia at 2 weeks.

Long-term oral aprindine (Table II): Follow-up of the 11 patients who had conversion to normal sinus rhythm with intravenous aprindine revealed that all had cure of ventricular tachycardia with oral aprindine. Nine of these patients (Cases 16 to 24) had incessant ventricular tachycardia. These nine were cured with oral aprindine therapy with a follow-up period of 1 to 38 months (mean 13 ± 12). Two patients (Cases 13 and 14) who had conversion to sinus rhythm with intravenous aprindine had paroxysmal sustained ventricular tachycardia with a frequency of 5 and 4 attacks/year, respectively, before the aprindine trial. Both patients were cured with oral aprindine, with no recurrence of ventricular tachycardia over a follow-up period of 37 and 17 months, respectively.

Two patients (Cases 1 and 2) with paroxysmal sustained ventricular tachycardia whose tachycardia slowed without conversion to sinus rhythm with intravenous aprindine but was not inducible after 2 weeks of oral aprindine therapy were followed up for 2 and 9 months, respectively, on oral aprindine therapy without recurrence of ventricular tachycardia.

Aprindine was discontinued in all but two of the remaining patients because of failure to achieve sinus rhythm at initial study and at 1 to 2 weeks (see earlier). Aprindine was administered chronically in two patients despite lack of successful response (Cases 8 and 9) because no other available therapy seemed preferable. Recurrent ventricular tachycardia developed in one of these patients (Case 9) despite aprindine, and one died (Case 8) approximately 1 month after initiation of oral aprindine.

Prediction of cure with oral aprindine (Fig. 3): The response to intravenous aprindine was an excellent predictor of the response to oral aprindine. All 11 patients who had conversion to sinus rhythm with intravenous aprindine were subsequently cured with oral aprindine, whereas only 2 of 14 patients who did not have conversion to sinus rhythm were cured with oral aprindine ($p < 0.001$). The response to intravenous aprindine predicted 11 of 13 possible cures (85 percent).

The pattern of ventricular tachycardia also predicted cure with oral (and intravenous) aprindine. Nine of 10 patients with incessant ventricular tachycardia were cured with oral aprindine compared with only 4 of 15 patients with paroxysmal sustained ventricular tachycardia ($p < 0.005$). Thus, the presence of incessant ventricular tachycardia predicted 9 of 13 possible cures.

Adverse effects: Twelve of the 25 patients manifested mild neurotoxicity after the oral dose of aprindine was established (7 with paroxysmal sustained and 5 with incessant ventricular tachycardia). The neurotoxicity consisted primarily of mild tremor or mild ataxia, or both. No patient manifested clinically significant aprindine hepatitis or agranulocytosis.

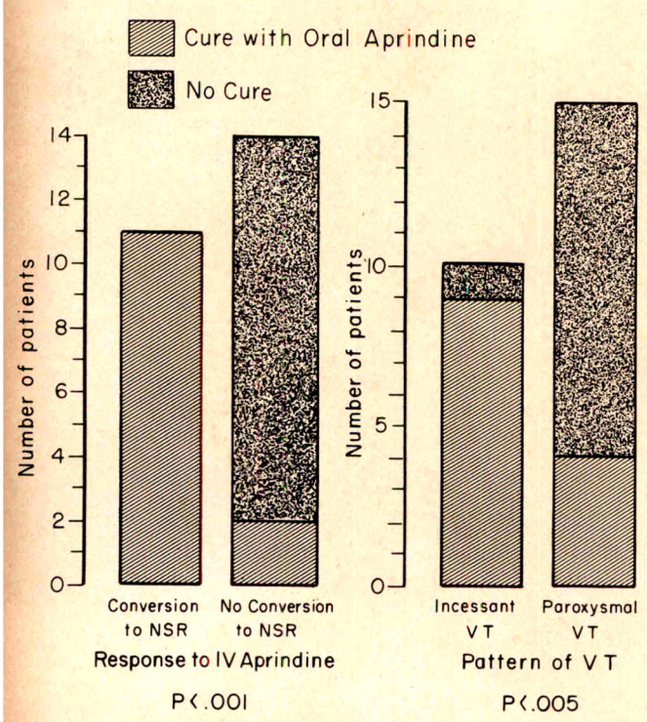

FIGURE 3. Prediction of cure of ventricular tachycardia according to response to intravenous (IV) aprindine (**left panel**) and pattern of ventricular tachycardia (VT) (**right panel**). See text for discussion. NSR = normal sinus rhythm.

Discussion

Aprindine is a potent antiarrhythmic agent currently available for use in Europe and now undergoing clinical investigation in the United States. One of the characteristics of aprindine is its long half-life of 13 to 50 hours[1]; therefore oral clinical trials of at least 1 week are necessary to reach full antiarrhythmic efficacy. The drug is well absorbed when given orally, and approximately 95 percent of the hydroxylated metabolites of aprindine undergo glucuronidation in the liver; 65 percent of the drug and its metabolites appear in small concentration in the plasma of patients on long-term therapy.[1,4]

Previous experience with aprindine: Aprindine has been used successfully in patients with a variety of supraventricular and ventricular arrhythmias.[5–10] Zipes et al.[6] recently emphasized its usefulness in refractory cases of supraventricular tachycardia incorporating accessory pathways (Wolff-Parkinson-White syndrome). Fasola et al.[11] reported on 23 patients with re-

current drug-resistant ventricular tachycardia and fibrillation; most of these patients had old myocardial infarction. After administration of aprindine no patient with ventricular fibrillation had recurrence of arrhythmia, and ventricular tachycardia was abolished in all but five patients; in three of the latter five patients ventricular tachycardia was of very short duration and slow rate, so that discontinuation of the drug was not necessary.

Wei et al.[12] described 10 patients with mitral valve prolapse and drug-refractory ventricular tachycardia; 4 of these patients had a history of ventricular fibrillation. In all 10 patients ventricular tachycardia was no longer observed after administration of aprindine. Additionally, 9 of the 10 patients had a 40 percent or greater reduction in the frequency of ventricular premature complexes. Troup and Zipes[13] also reported on seven patients with mitral valve prolapse and recurrent drug-refractory ventricular tachycardia. In all patients, ventricular tachycardia was abolished during long-term aprindine therapy and a 91 percent reduction was observed in the total number of premature ventricular complexes per 24 hours.

Intravenous versus oral aprindine: Because of the long half-life of aprindine, a 1 to 2 week oral trial is necessary to determine clinical efficacy. A similar response of arrhythmia to both intravenous and oral aprindine would be of great clinical significance, because the intravenous response can be obtained in one relatively short testing period.

In most previous reports, aprindine was administrated intravenously or orally, or both, but not systematically to all patients by both routes. In the present study, our overall rate of success was 52 percent (13 of 25 patients), which is an acceptable rate considering that all of these patients were refractory to conventional antiarrhythmic agents. Patients who did not have conversion to sinus rhythm with intravenous aprindine manifested a reduction either in rate (13 patients) or in frequency (1 patient) of ventricular tachycardia (Fig. 2). Both of these responses improved the patient's hemodynamic status; thus in two patients in whom no other modality of therapy was available, aprindine was given as long-term oral therapy. The majority of patients receiving long-term oral therapy manifested adverse central nervous system effects, but in all patients a dose was achieved whereby these effects, if any, were well tolerated and cure of ventricular tachycardia was still present.

Eleven patients who had conversion to sinus rhythm with intravenous aprindine were subsequently cured with oral aprindine, whereas 2 of 14 patients who did not have conversion with intravenous aprindine were subsequently cured with oral aprindine. Intravenous aprindine predicted 83 percent of the cures (Fig. 3, left panel). Nine of the 11 patients who had conversion to sinus rhythm with intravenous aprindine had incessant ventricular tachycardia (9 of the 10 patients with incessant ventricular tachycardia). Only 2 of the 11 patients who had conversion to sinus rhythm with intravenous aprindine had paroxysmal sustained ventricular tachycardia, and only 4 of the 15 patients with paroxysmal sustained ventricular tachycardia were cured with oral aprindine (Fig. 3, right panel).

The explanation for these responses deserves some comment. It is not surprising that the response to intravenous aprindine predicts the response to oral aprindine because in our experience, electrophysiologic testing of intravenous drugs in patients with paroxysmal supraventricular tachycardia often predicts the response to oral agents.[3] It is not clear why, in the present study, occasionally responses were achieved with oral aprindine that were not achieved with intravenous aprindine. In these instances, the tissue drug level achieved with oral loading for 1 to 2 weeks may be greater than that achieved with intravenous loading.

It is not clear why patients with incessant ventricular tachycardia tend to respond to aprindine, whereas those with paroxysmal sustained ventricular tachycardia do not. The pathophysiologic characteristics of the former arrhythmia are not clear to us, whereas the latter appears to be reentrant (using commonly accepted criteria). Until the pathophysiologic features of ventricular tachycardia and the pharmacologic features of aprindine are further elucidated, the answers to these questions will probably remain elusive.

Clinical implication: Our study suggests several conclusions. Administration of intravenous aprindine to patients with ventricular tachycardia is helpful in predicting the subsequent response to oral aprindine. Specifically, conversion of ventricular tachycardia to sinus rhythm with intravenous aprindine predicts cure of ventricular tachycardia with oral aprindine. Failure of conversion with intravenous aprindine usually predicts failure of therapy with oral aprindine.

The pattern of ventricular tachycardia is also useful in predicting the response to both intravenous and oral aprindine. Patients with incessant ventricular tachycardia are likely to have conversion to normal sinus rhythm with intravenous aprindine and have permanent conversion with oral aprindine. In contrast, in patients with paroxysmal sustained ventricular tachycardia a favorable response to either intravenous or oral aprindine is unusual. It is our opinion that administration of intravenous aprindine should be utilized as a test before embarking on oral aprindine therapy in patients with recurrent ventricular tachycardia. Since a few patients respond successfully only to oral (and not to intravenous) administration of aprindine, oral aprindine can be given to patients with ventricular tachycardia who do not respond to intravenous aprindine. However, in the latter situation, cure with oral aprindine therapy will usually not be achieved.

Original Topical Predictable Titratable Flexible

Nitrol (nitroglycerin ointment, 2%) and sublingual tablets are ideal companions for treatment of angina pectoris. Tablets work immediately, but results are fleeting. Nitrol acts rapidly (15 minutes), and the consistent, beneficial effects are sustained for up to four hours.

Because Nitrol is an ointment, you can titrate dosage to provide the exact amount of nitroglycerin needed to bring predictable long-lasting pain relief to individual patients.

The clinical efficacy of Nitrol – the original nitroglycerin ointment – has been confirmed in 18 published studies. It is a therapy whose time has come...for your angina pectoris patients.

Nitrol®
(nitroglycerin ointment, 2%)

DESCRIPTION: 2% Nitroglycerin (glyceryl trinitrate) in a special lanolin-petrolatum base. Each inch (approx. 750 mg) of NITROL Ointment contains 15 mg of nitroglycerin.

CLINICAL PHARMACOLOGY: When the ointment is spread on the skin, the active ingredient (nitroglycerin) is continuously absorbed through the skin into the circulation, exerting prolonged vasodilator effect, regardless of the site of application.

Nitroglycerin relaxes smooth muscles and dilates the arterioles and capillaries, especially in the coronary circulation. This allows increased blood supply to the myocardium, tending to relieve myocardial ischemia. NITROL Ointment produces peripheral vasodilation with decreased arteriolar resistance and increased volume and favorably affects peripheral vascular resistance, venous capacitance, preload and afterload which may be the basis of its action in angina pectoris. Nitroglycerin favorably influences myocardial oxygen consumption, resulting in increased myocardial efficiency and significant improvement in left ventricular function. NITROL Ointment also produces sustained, enhanced exercise capacity; attenuation of ischemic EKG changes; concomitant changes in heart rate and blood pressure without evidence of tolerance or toxicity. Hemodynamic alterations are similar to those of sublingual nitroglycerin, but onset (15 minutes) is delayed and the effect (up to 4 hours) is prolonged. Recent clinical studies in hospitalized patients, however, suggest the duration of NITROL Ointment to be eight hours.

INDICATIONS: Prevention and treatment of angina pectoris associated with or resulting from coronary insufficiency, coronary artery disease, coronary occlusion, or subacute myocardial infarction.

CONTRAINDICATIONS: Contraindicated in patients with marked anemia, increased intraocular pressure or increased intracranial pressure; or in patients with known idiosyncrasies to nitrites.

WARNING: In terminating treatment, both the dosage and frequency of application must be gradually reduced over a period of 4 to 6 weeks to prevent sudden withdrawal reactions, which are characteristic of all vasodilators in the nitroglycerin class.

PRECAUTIONS: Hypotensive headache is a sign of overdosage. Elderly patients may have no untoward symptoms while recumbent but may develop postural hypotension with faintness upon suddenly arising. The dosage should be reduced in these patients.

It is not known whether nitroglycerin can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. Nitroglycerin should be given to a pregnant woman only if clearly needed.

ADVERSE REACTIONS: Transient headaches, which may be treated with mild analgesics. Dosage may be reduced in those patients experiencing persistent headache. Tachycardia, dizziness, flushing, although uncommon, may occur.

Contact dermatitis has been reported with continuous use of topical nitroglycerin. Such incidences may be reduced by changing the site of application or by using topical corticosteroids.

DRUG ABUSE AND DEPENDENCE: Experience has revealed no evidence of drug abuse and dependence associated with use of NITROL Ointment.

MANAGEMENT OF OVERDOSAGE: Should hypotension resulting from overdosage develop, quickly remove the ointment. Severe hypotension usually responds to the administration of phenylephrine HCl or levarterenol bitartrate.

DOSAGE AND ADMINISTRATION: For angina pectoris: Apply every 3 to 4 hours as required. Usual dose, 1 to 2 inches squeezed from the tube, although some patients may require as much as 4 or 5 inches. Spread over approximately 2" x 3" area in a thin, uniform layer on the skin. Optimum dosage is determined by starting with an application of ½ inch of ointment and increasing the dose in ½ inch increments each successive application until headache occurs, then decreasing to the largest dose which does not cause headache. Apply to any convenient skin area. Psychologically, many patients prefer the chest. Measurement and application is easily accomplished with the aid of the specially designed Appli-Ruler™ supplied with the ointment. Squeeze ointment onto the graduated area of the Appli-Ruler and spread over the desired skin area. Keep the tube tightly closed and store at controlled room temperatures.

Quinton

INTRODUCING STATUS 1000

WITH AN IMAGINATION TO MATCH YOUR OWN

Status 1000, The ECG Monitor That Gives You Programmable Control Over Every Aspect Of The Stress Test.

Quinton's Status 1000 is the first ECG stress test system that lets you use your imagination to modify or reprogram at will the various elements of a stress test.

Not just treadmill protocol, but lead selection, ST sample point, recorder speed, patient name, final report content and length, blood pressure prompting, etc. Everything is in your control like it should be.

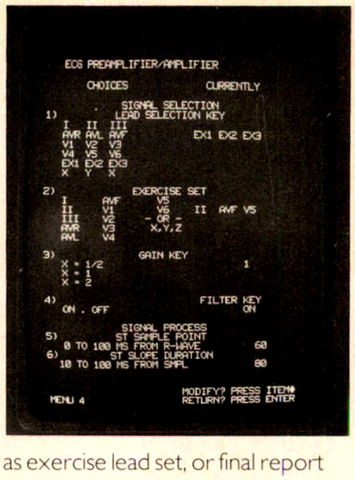
Use your professional imagination to create and program customized test procedures for pediatric, research, post-M.I., rehab., or out-patient situations.

Each physician in your institution can have their own preferred test procedure stored in memory.

With the Status 1000 you and your colleagues can customize test procedures based on the requirements of the patient, not the restrictions of the ECG system.

How The Sophisticated Status 1000 Makes Test Flexibility So Complete And Easy

With The Status 1000, Quinton introduces a new term, the "Stress Test Environment". It consists of 16 test elements. Each element, such



as exercise lead set, or final report content, has parameters which you can establish or modify to suit your needs.

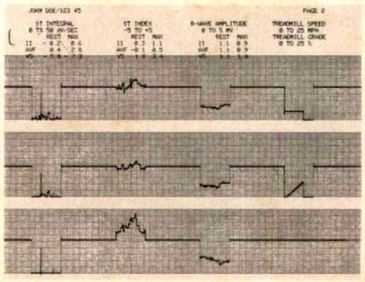
Yet, programming the Status 1000 is as easy as operating a pocket calculator, so special training is not required.

Comprehensive Data, Professionally Presented

In a single glance you see three channels of diagnostic quality ECG, averaged beats (both resting and current), heartrate, computed parameters, trend displays, stage number, stage time and elapsed time.

Plus, any abnormal beat will be instantly highlighted on the screen, then recorded and labeled automatically.

Your control extends to test reports, too. Printouts during the test may include averaged beats, rhythm strips, or full 12-leads. Final reports may include a wide variety of information. And each report is automatically labeled with pertinent data. Good bye work sheet.



Stay Ahead With The Status 1000

Because of the Status 1000's unparalleled flexibility and microprocessor technology its susceptibility to obsolescence is far less than other systems. And that makes it a good investment for you and your institution. Call Quinton toll free at 1-800-426-0538.

Laragh's eagerly awaited new guide to understanding, diagnosing, and treating Hypertension *in its many forms...*

TOPICS IN HYPERTENSION

Edited by JOHN H. LARAGH, MD

Master Professor of Medicine, Chief, Cardiology Division
Director, The Cardiovascular Center
The New York Hospital-Cornell Medical Center

High blood pressure is no longer only a problem of worldwide interest and relevance. It is now one in which the knowledge base has exploded to the point where the informed physician can do more and more about it in his daily practice . . . and can apply, to an ever-increasing extent, more sophisticated and individually tailored therapies.

Laragh's TOPICS IN HYPERTENSION places this kind of vital knowledge within instant reach of the physician. It presents a carefully selected array of discussions by 85 eminent specialists. It deals in depth with recent breakthroughs in understanding, diagnosing, and treating this problem.

The book is conveniently organized for effective consultation and reading.

Check the helpful contents...

SECTION 1
Some Biochemical and Pathophysiologic Aspects
1 The Biochemistry of the Renin-Angiotensin System and Its Role in Hypertension **2** Conversion of Angiotensin I to Angiotensin II **3** Angiotensin Receptors in Vascular Tissue **4** Vascular Angiotensin Receptors and Their Role in Blood Pressure Control **5** Renal Prostaglandins and the Regulation of Blood Pressure Renin Release and Sodium and Water Homeostasis **6** Linking the Kallikrein and Renin Systems via Activation of Inactive Renin: New Data and a Hypothesis **7** Control of Renin Release: Experimental Evidence and Clinical Implications **8** Blood Rheology in Hypertension and Cardiovascular Diseases **9** Renal Circulation in Hypertensive Disease **10** The Concept of Autoregulation of Total Blood Flow and Its Role in Hypertension **11** A Proposed Cybernetic System for Sodium and Potassium Homeostasis: Coordination of Aldosterone and Intrarenal Physical Factors

SECTION 2
Newer Physiologic Approaches to Diagnosis
12 Renin-Sodium Profiling: Why, How and When in Clinical Practice **13** How to Do a Plasma Renin Assay **14** The Renin Axis and Vasoconstriction Volume Analysis for Understanding and Treating Renovascular and Renal Hypertension **15** Clinical and Laboratory Diagnosis of Adrenocortical Hypertension

SECTION 3
Clinical and Prognostic Aspects
16 High Blood Pressure in Children: Problems and Guidelines for Evaluation and Treatment **17** Systolic Hypertension: Nonhomogeneous Diseases **18** Hypertension Associated with Early Stage Kidney Disease **19** Elevation of Serum Lipid Levels During Diuretic Therapy of Hypertension **20** Renin and Aldosterone Secretion in Pheochromocytoma: Effect of Chronic Alpha Adrenergic Receptor Blockade **21** Pathogenesis of Hypertension in Cushing's Syndrome: Glucocorticoid Excess **22** The Renin-Sodium Profile as a Predictor of Hypertensive Complications **23** The Hypertensive Diseases

SECTION 4
Modes of Therapy
PART I ***Beta Blockade***
24 Acute and Long-term Studies of the Mechanisms of Action of Beta Blocking Drugs in Lowering Blood Pressure **25** The Role of Beta Adrenoreceptor Blockade in Hypertension **26** Rapid Identification of Patients with Essential Hypertension Sensitive to Beta Blockade **27** The Predictive Value of Renin Profiling in the Choice of Treatment in Primary Hypertension, with Special Reference to Patients with Low Renin Values **28** Prazosin: An Alpha Adrenergic Blocking Agent in Treatment of Hypertension **29** Antihypertensive Effectiveness of Propranolol: Role of the Renin-Aldosterone Axis **30** Antihypertensive Beta Blocking Action as Related to Renin and Age: A Pharmacologic Tool to Identify Pathogenetic Mechanisms in Essential Hypertension **31** Modern System for Treating High Blood Pressure Based on Renin Profiling and Vasoconstriction-Volume Analysis: A Primary Role for Beta Blocking Drugs such as Propranolol

PART II ***Saralasin***
32 Usefulness and Limitations of Saralasin, a Partial Competitive Agonist of Angiotensin II, for Evaluating the Renin and Sodium Factors in Hypertensive Patients **33** Angiotensin Blockade: Its Clinical Significance

PART III ***Converting Enzyme Blockade: Basic and Clinical Aspects***
34 The Renin System in High Blood Pressure: Converting Enzyme Blockade for Analysis and Treatment **35** Estimating Renin Participation in Hypertension: Superiority of Converting Enzyme Inhibitor over Saralasin **36** Clinical Experience with Blockade of the Renin-Angiotensin-Aldosterone System by an Oral Converting Enzyme Inhibitor (Captopril) in Hypertensive Patients

Pfizer Laboratories
invites you to attend
an Educational Symposium:*

Nifedipine in Ischemic Heart Disease: The International Experience

Chairman:
Dennis Krikler, M.D., F.A.C.C.
Consultant Cardiologist
Royal Postgraduate Medical School
Hammersmith Hospital, London, England

The symposium immediately follows the 30th Annual Scientific Session of the American College of Cardiology and will be held in:

The Imperial Ballroom of
The San Francisco Hilton Hotel
333 O'Farrell St., San Francisco, California

March 19, 1981
1:30-5:30 P.M.

If you would like to attend the symposium and have not yet registered, please do so at the Pfizer booths #2004, 2005 and 1101 at Brooks Hall during the American College of Cardiology Session.

*Science & Medicine is assisting in the organization of the symposium under an educational grant from Pfizer Laboratories.

Nifedipine in the Management of Ischemic Heart Disease: The European Experience

MODERATOR: **Eugene Braunwald, M.D., F.A.C.C.**
Hersey Professor of the Theory and Practice of Medicine
Harvard Medical School

TOPICS:

- Moderator's Introduction — **Eugene Braunwald, M.D., F.A.C.C.**
- Calcium Channel Blockers: A New Concept in Cardiologic Treatment — **Dennis Krikler, M.D., F.A.C.C.**

Introduction: The Functionally Integrated Cardiovascular-Pulmonary Unit

RICHARD A. MATTHAY, MD
LAWRENCE D. H. WOOD, MD

New Haven, Connecticut
Winnipeg, Manitoba, Canada

Respiratory failure is usually defined on the basis of alterations in arterial blood gas composition: an arterial oxygen tension less than 60 mm Hg or an arterial carbon dioxide tension greater than 50 mm Hg, or both. Abnormalities leading to respiratory failure are multiple, ranging from disturbances in the control of breathing (for example, drug overdose) to impaired function of the airways (acute bronchial asthma) to disorders of the lung parenchyma (pneumonia).[1] A major goal in the treatment of patients with respiratory failure has been to provide adequate tissue oxygenation. Oxygen delivery to tissues is the product of blood oxygen content and cardiac output. Until recently, patients with acute respiratory failure, particularly those with the adult respiratory distress syndrome, died rapidly of hypoxemia with markedly depressed arterial and venous oxygen contents and severe venous admixture. However, advances in respiratory care, including mechanical ventilation with positive end-expiratory pressure, have reversed hypoxemia and have extended the life span of patients with acute respiratory failure.[2,3] Thus, patients who reach an intensive care unit now seldom die simply of hypoxemia.[4]

Yet, mortality from respiratory failure remains high. Between 1973 and 1976, the mortality rate from adult respiratory distress syndrome at San Francisco General Hospital was 53 percent.[1] At the Beth Israel Hospital in Boston, among all patients who required mechanical ventilation due to respiratory failure the mortality rate was approximately 20 percent.[5] Clearly other factors than hypoxemia, which can now be corrected in most patients, must be contributing to mortality in patients with respiratory failure.[1,2,4]

From the Pulmonary Section, Department of Internal Medicine, Yale University School of Medicine, New Haven: Connecticut and the Section of Respiratory Diseases, Department of Internal Medicine, University of Manitoba, Winnipeg, Canada. Manuscript received October 1, 1980, accepted December 1, 1980.

Address for reprints: Richard A. Matthay, MD., Department of Internal Medicine, LCI 101, Yale University School of Medicine, 333 Cedar Street, New Haven, Connecticut 06510.

Recently, marked abnormalities in cardiovascular function have been identified in patients with both acute and chronic respiratory failure, and each of these abnormalities may have adverse effects on tissue oxygen delivery and on patient outcome. Among these cardiovascular disturbances are pulmonary arterial hypertension and elevated pulmonary vascular resistance, depressed right and left ventricular performance, and reduced cardiac output.[2,4–13] Intrathoracic pressure changes,[13,14] which occur in acute and chronic respiratory insufficiency, may affect myocardial pump performance, blood return to the right heart chambers, cardiac output and, hence, oxygen delivery to tissue. Moreover, it is now evident that mechanically assisted ventilation and positive end-expiratory pressure may exert adverse effects on the cardiovascular system[7,11,13–15] while simultaneously improving arterial oxygen tension and content in acute respiratory failure. Correcting arterial hypoxemia alone may be inadequate, and methods utilized to improve arterial oxygenation may adversely affect the cardiovascular system and ultimately patient survival. Accordingly, in treating patients with respiratory insufficiency, it is imperative to consider the heart and lungs together as a functionally interrelated cardiovascular-pulmonary unit. Evolving appreciation of this concept formed the basis of the reports[16–20] in this Seminar, which reviews the relation among systemic vessels, the heart and the lungs in acute and chronic respiratory failure.

Contractile Mechanics and Interaction of the Right and Left Ventricles

The first paper of the Seminar[16] discusses myocardial contractile mechanics and the interrelation between the right and left ventricles within the context of the functional cardiopulmonary unit. As Weber et al.[16] describe it, the cardiopulmonary unit consists of three anatomic subunits: "two in-series muscle pumps, the right and left heart chambers, which are mechanically coupled by the lungs." The anatomic arrangement and mechanical

interaction of these three subunits facilitate their functional integration. Thus, the interventricular septum and the pericardium promote interaction between ventricles, while intrathoracic pressure or pleural pressure envelops the entire unit, creating an additional interaction between the ventricles and the heart and lungs.

Viewing the heart as an integral part of the cardiopulmonary unit, Weber et al. review three aspects of myocardial mechanics: (1) the concept of wall force and stress, (2) the isovolumetrically beating ventricle, and (3) the ejecting ventricle. They present data from studies with the isolated heart preparation that show interaction between the right and left ventricles during both diastole and systole. Moreover, the position and motion of the interventricular septum, regulated by the transseptal force gradient, is shown to be critical in determing this interaction. Finally, they discuss the influence of both intrapericardial and intrathoracic pressures on transmural pressure and thus on myocardial function. Respiratory failure is associated frequently with stiff lungs and requirement for mechanical ventilation, both of which can cause marked swings in intrathoracic pressure and transmural pressures. In such a setting, effects on myocardial pumping function may be dramatic.

Role of Systemic Vessels in Control of Cardiac Output

In the next paper, Goldberg and Rabson[17] review determinants of venous flow to the heart: (1) mean pressure in the systemic vasculature, (2) right atrial pressure, and (3) resistance to venous return. Although these concepts have previously been elucidated, they have not received considerable clinical attention in the setting of respiratory failure. The major focus has been directed toward cardiovascular disturbances in respiratory failure in which the heart is damaged and itself limits cardiac output. However, in patients with acute or chronic respiratory failure without cardiac dysfunction, factors governing venous return may be important in causing disturbances of cardiovascular function. Moreover, as Goldberg and Rabson indicate, several therapeutic modalities employed in respiratory failure may affect the relation between mean systemic pressure and right atrial pressure, thereby altering venous return to the heart and cardiac output.[17] Some of these modalities include positive pressure (mechanical) ventilation, diuretics, cardiac glycosides and other inotropic or vasoactive drugs.

Cardiovascular Disturbances in Chronic Respiratory Insufficiency

In the third paper, Robotham[18] applies the physiologic concepts of the functional cardiopulmonary unit and venous return discussed in the first two papers[16,17] to patients with chronic respiratory insufficiency. How mechanical factors in chronic respiratory insufficiency influence right and left ventricular performance, venous return and cardiac output during both spontaneous and mechanical ventilation is discussed. Further, Robotham reviews several factors present during intermittent positive pressure ventilation that act together to improve left ventricular performance in respiratory failure despite concomitant adverse effects on right ventricular performance.

Noninvasive Radiographic Assessment of Cardiovascular Functions in Acute and Chronic Respiratory Failure

In the fourth paper of this Seminar Berger and Matthay[19] critically review recent advances in noninvasive assessment of cardiovascular performance in respiratory failure. They discuss three noninvasive modalities for evaluating the cardiovasculature: (1) the plain chest radiograph, (2) radionuclide imaging, and (3) echocardiography. Moreover, they present data establishing the clinical applicability of these techniques in patients with acute and chronic respiratory failure. Their data demonstrate the ability of radionuclide angiocardiography (1) to detect clinically inapparent right and left ventricular performance abnormalities, and (2) to detect alterations in biventricular performance after therapeutic intervention in patients with respiratory failure.

Cardiovascular Management in Acute Hypoxemic Respiratory Failure

The last paper attempts to apply the concepts and methodologies described in previous seminar papers to the clinical problems of low pressure pulmonary edema. Wood and Prewitt[20] review aspects of the treatment of cardiogenic pulmonary edema in which classic therapeutic aims are to lower pulmonary vascular pressures and to increase cardiac output. They extend these principles to low pressure edema, in which small reductions in pulmonary wedge pressure reduce edema, yet similar increases in circulating colloid osmotic pressure do not. They propose a therapeutic goal of the lowest pulmonary wedge pressure consistent with adequate cardiac output, using colloid to maintain sufficient circulating volume but not to reduce edema. When cardiac output becomes insufficient as pulmonary wedge pressure is reduced, vasoactive agents may be used to return cardiac output to normal without increasing wedge pressure or edema. Their review of the effects of vasoactive agents on pulmonary oxygen exchange suggests that pulmonary vasoactivity of these drugs does not increase shunt. Further, they conclude that positive end-expiratory pressure does not depress ventricular function.

Because positive end-expiratory pressure reduces pulmonary shunt by redistributing but not reducing pulmonary edema, they contend that the least positive end-expiratory pressure required to achieve 90 percent oxygen saturation of an adequate circulating hemoglobin on a nontoxic inspired oxygen concentration is a reasonable therapeutic objective. Finally, they emphasize that many of their conclusions are based on

canine data requiring clinical trials for validation, and they point out that many investigative methods described in previous Seminar papers are now available to test such therapeutic hypotheses.

Contractile Mechanics and Interaction of the Right and Left Ventricles

KARL T. WEBER, MD, FACC*
JOSEPH S. JANICKI, PhD*
SANJEEV SHROFF, MS
ALFRED P. FISHMAN, MD, FACC

Philadelphia, Pennsylvania

The heart and lungs, together with hemoglobin, provide for the transport of oxygen from the atmosphere to the metabolizing tissue. The oxygenation of blood and the circulation of oxygenated blood are precisely synchronized so that the heart and lungs constitute an integrated cardiopulmonary unit. The functional integration of the heart and lungs is fostered by their anatomic arrangement and mechanical interaction.

The cardiopulmonary unit consists of the right and left ventricles (two in-series pumps composed of cardiac muscle), which are mechanically coupled by the lungs. The factors that control cardiac muscle shortening (fiber length, afterload and myocardial contractile state) also regulate the pumping behavior of each ventricle. Because the ventricles are aligned in series a perturbation in the mechanical events of one ventricle will influence the behavior of the other ventricle. The interventricular septum and pericardium further promote the mechanical interplay between ventricles. Intrathoracic pressure (the pressure that surrounds the cardiopulmonary unit) creates an additional interaction between the ventricles as well as the heart and lungs.

The heart and lungs, together with hemoglobin, provide for the transport of oxygen from the atmosphere to the metabolizing tissues. Normally, the oxygenation of blood and the circulation of oxygenated blood are precisely synchronized so that the heart and lungs constitute a functionally integrated cardiopulmonary unit designed for oxygen transport.

This cardiopulmonary unit consists of three anatomic subunits: two in-series muscle pumps, the right and left ventricles, which are mechanically coupled by the lungs (Fig. 1). The functional integration of these subunits is fostered by their anatomic arrangement and mechanical interaction. The mobile interventricular septum and pericardium promote the interaction between ventricles, while intrathoracic or pleural pressure surrounds the entire unit and creates a second interaction between the ventricles as well as the heart and lungs. It will be the purpose of this review to consider specifically the contractile mechanics and interaction of the two pumps and their integration within the cardiopulmonary oxygen transport unit. An understanding of the physiologic behavior of the cardiopulmonary unit will provide critical insight into the clinical recognition and management of the patient with respiratory failure.

The Heart As a Muscular Pump

The myocardium is a syncytium of muscle fibers tethered within a supportive network of collagen. The contraction or shortening of these muscle fibers results in the generation of pressure within the ventricular chambers, thickening of the wall and a reduction in ventricular volume. The factors that control muscle fiber shortening also control the pumping behavior of the ventricle and, hence, we may view the heart as a muscular pump.[1]

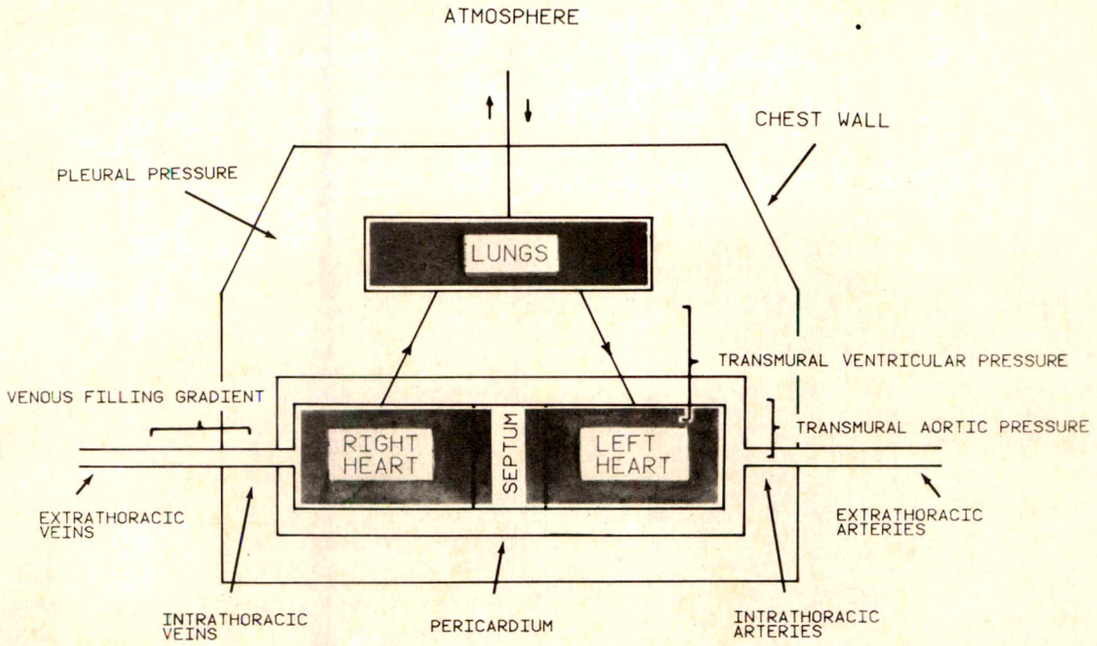

FIGURE 1. The cardiopulmonary unit consists of the right and left heart chambers mechanically coupled by the lungs and enclosed within the thorax. The pericardium, interventricular septum and pleural pressure contribute to the mechanical interaction of the two ventricles and the heart and lungs.

The Concept of Wall Force and Stress

Wall force: In isolated cardiac muscle it is well known that muscle length and muscle shortening are a function of the external force that exists on the muscle before and during its contraction, respectively. In the intact heart in which the arrangement of muscle fibers is complex, an approximation of force is needed; *however, ventricular pressure alone is not an adequate description of force.* A net *force* (grams) existing across the myocardial wall in any particular plane can be derived from the product of chamber pressure (g/cm^2) and the cross-sectional area (cm^2) of the chamber included in the plane.[1,2] The load on the muscular wall and its muscle fibers therefore is a function of both chamber pressure and the configuration of the chamber. As a case in point, the myocardium surrounding the enlarged ventricle has to develop more force to generate a given level of pressure than does the normal-sized heart. In similar fashion the force that exists at the apex of the ventricle will be less than that along its equator.

Wall stress: Force per unit of cross-sectional area of the myocardium (g/cm^2) represents wall *stress.* Wall thickness is presumed to be a function of regional wall force[3]; hence, stress is homogeneously distributed throughout the ventricle (for example, the smaller force at the apex is distributed over a thinner area of myocardium), thereby favoring uniform wall motion.

One would also predict that stress is uniformly distributed across the interventricular septum. However, septal stress will be a function of the right and left ventricular forces acting on the septal surfaces. A marked gradient in transseptal surface forces would promote a shift of the septum to the chamber with less force and potentially obliterate this ventricle (Fig. 2). As is the case with the free wall of either ventricle, it is not satisfactory to consider pressure or the gradient in pressure across the septum as the sole factor regulating its position. For example, the systolic pressure in the left ventricle is normally five times that in the right ventricle and yet the integrity of the right ventricular chamber is maintained. However, an acute increase in chamber size, such as may occur in the right ventricle with marked negative intrathoracic pressure, will induce a gradient and shift the septum toward the left ventricle (Fig. 2). Septal displacement, which occurs as a result of the disturbance in the transseptal gradient in force, will also be accompanied by changes in shape and size of each ventricle and their effective compliance. For example, a leftward shift of the septum (that is, toward the left ventricle) decreases the septal to left ventricular free wall dimension while increasing the anteroposterior dimension (Fig. 2). This alteration in chamber configuration contributes to the change in filling volume and pressure (distensibility) associated with fluctuations in intrathoracic pressure. During inspiration the right ventricle becomes more distensible as a result of the leftward shift of the septum and therefore can accommodate the increased venous return and filling volume without a change in diastolic pressure. In contrast, the distensibility of the left ventricle is reduced. However, because the left ventricle is now stiffer, the filling pressure of this chamber may remain invariant, despite a reduction in filling volume.

Preload and afterload: The magnitude and time course of wall force and stress vary throughout the cardiac cycle.[1] At end-diastole, the diastolic configu-

ration and pressure of either ventricle determine the distending force, or *preload,* on its wall. Preload determines muscle fiber length before contraction. Depolarized myocardium begins to contract, leading to the generation of pressure within the chamber. When chamber pressure exceeds that of the corresponding pulmonary or systemic circulation the ejection of blood commences. The force the myocardium must support during ejection, the *afterload,* is a function of the corresponding change in chamber configuration and pressure. Normally, afterload peaks shortly after the onset of ejection. However, because chamber size decreases more than pressure increases, afterload decreases during the remainder of ejection. Hence, the heart is normally able to partially unload itself during its contraction. Moreover, it should be apparent that a single value for force will not adequately describe afterload. The importance of the instantaneous variation in afterload is dramatized even further in the dilated and failing ventricle in which the reduction in chamber size during ejection is minimal. In this case the afterload trajectory becomes abnormal and, in fact, may increase rather than decrease during ejection.[1]

The Isovolumetrically Beating Ventricle

Cardiac muscle can generate force without muscle shortening (that is, an isometric contraction in which muscle length does not change). In the intact heart a contraction without the displacement of blood from the ventricle (for example; when the aortic valve is sewn together) is termed *isovolumetric.* The isovolumetrically beating heart can be used to describe the maximal force the myocardium can generate from a given volume. The greater the chamber volume, the larger the developed force, where force again is equal to the product of chamber pressure and the cross-sectional area of the chamber. This relation describes the Frank-Starling, or length-dependent, property of cardiac muscle. This slope of the maximal force-volume relation, which can be derived from a series of isovolumetric contractions of different filling volumes (Fig. 3), describes the contractile state of the myocardium. A nonparallel shift in the slope of this relation is created by an alteration in contractile state.[4,5] For example, a catecholamine will increase (Fig. 4) and propranolol will reduce this slope. Hence, for any given chamber volume the maximal force the myocardium is able to support is determined by the contractile state-dependent isovolumetric force-volume relation.

The Ejecting Ventricle

Pressure-volume relation: The contractile state-dependent isovolumetric force-volume relation also pertains to the ejecting ventricle in that this relation determines the limit to chamber volume displacement.[6] In Figure 4 the pressure-volume events for isovolumetric and ejecting contractions are shown for the right and left ventricles. In the ejecting ventricle, pressure is

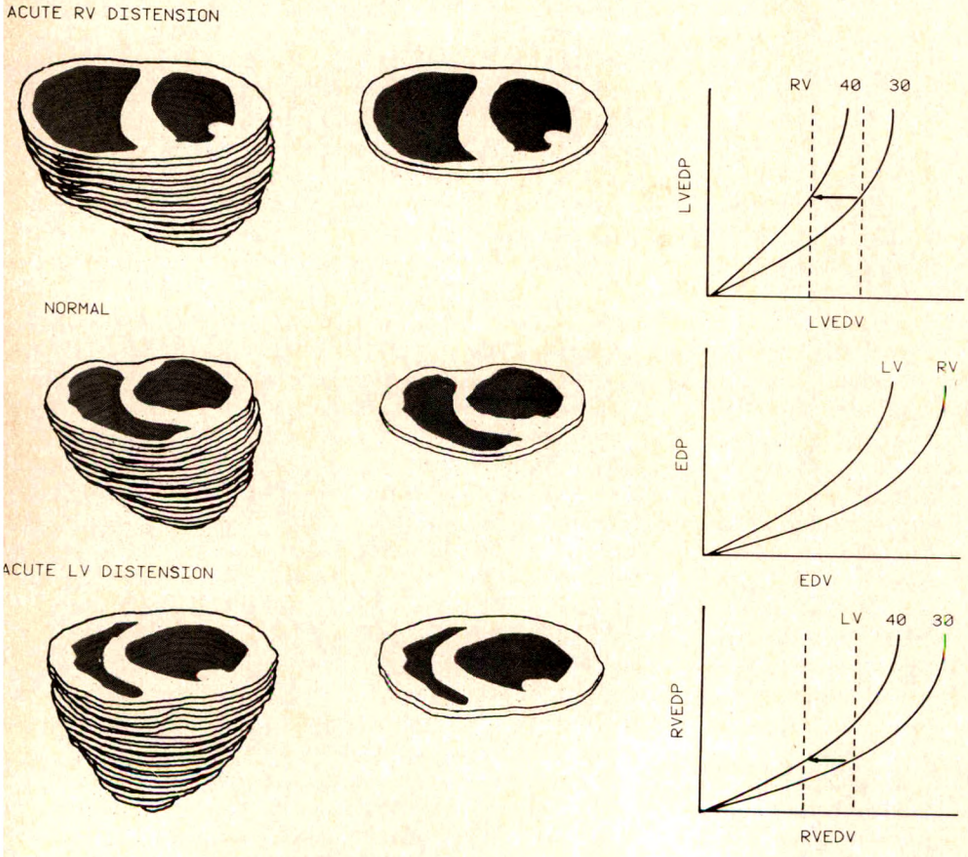

FIGURE 2. A computer reconstruction of the normal canine heart (**middle panel**) whose right and left ventricles were fixed at 6 and 12 cm H_2O, respectively. As depicted in the corresponding diastolic pressure-volume relation, the right ventricle (RV) is twice as distensible as the left ventricle (LV). With the acute distension of one ventricle, the interventricular septum is shifted toward the other ventricle. Because of this septal displacement the shape and distensibility of each ventricle are altered. For example, the greater the right ventricular volume (pressure-volume relation, **upper right**) the less distensible is the left ventricle. Because the left ventricle is now stiffer, its volume can decrease (**arrow**) without the occurrence of a change in filling pressure. EDP and EDV = end-diastolic pressure and volume, respectively; LVEDP and RVEDP = left and right ventricular end-diastolic pressure, respectively; LVEDV and RVEDV = left and right ventricular end-diastolic volume, respectively.

generated from end-diastole (point a) to the onset of ejection (point b) during the isovolumic phase of contraction; during ejection, ventricular volume decreases. When a systolic pressure is attained that is maximal for the given systolic chamber volume, ejection will cease (point c). This relation also pertains to the more accurate notation of load or wall force.[6] By increasing or decreasing contractile state, and thereby the slope of the maximal force-volume relation, the extent to which the ventricle is able to displace volume (that is, its stroke volume) for any afterload will correspondingly either increase (point c′ in Fig. 4) or decrease. Parallel shifts in the maximal force-volume relation occur independently of changes in contractile state. These shifts are the result of ventricular interaction.[7] For example, with right ventricular distension, the left ventricle is able to generate a greater force from any given volume (Fig. 5) because the interventricular septum has been shifted leftward, thereby minimizing the energy lost to septal movement.

Preload versus afterload: We have now established the limit of ventricular ejection and the importance of myocardial contractile state in determining this limit. Two other properties of cardiac muscle will determine the stroke volume from either ventricle. These include (1) the force that opposes fiber shortening, and (2) the length of cardiac muscle.[4,5,8] The greater the afterload opposing ejection the less the degree of shortening and chamber volume displacement (Fig. 6). This is true for both the right and left ventricles. Again recall that afterload is determined by both systolic pressure and chamber configuration during ejection. An excessive afterload may occur not only in aortic or pulmonary stenosis and systemic or pulmonary hypertension in which systolic pressure is increased, but also in the dilated failing ventricle (see earlier).

The filling volume and pressure of the ventricle are responsible for determining muscle length (preload) and the capacity of the ventricle to displace blood. Normally, for any given afterload, the larger the volume of the ventricle at the onset of ejection, the greater will be its stroke volume (Frank-Starling property of the heart). In the diseased heart the ventricle dilates in compensatory fashion to maintain pump function. However, a

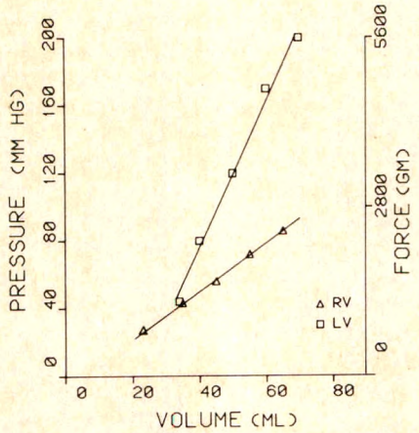

FIGURE 3. The pressure-volume and force-volume relations for the isovolumetrically beating right (RV) and left (LV) ventricles. Force was calculated from the product of ventricular pressure and the cross-sectional area of the left and right ventricular chambers.

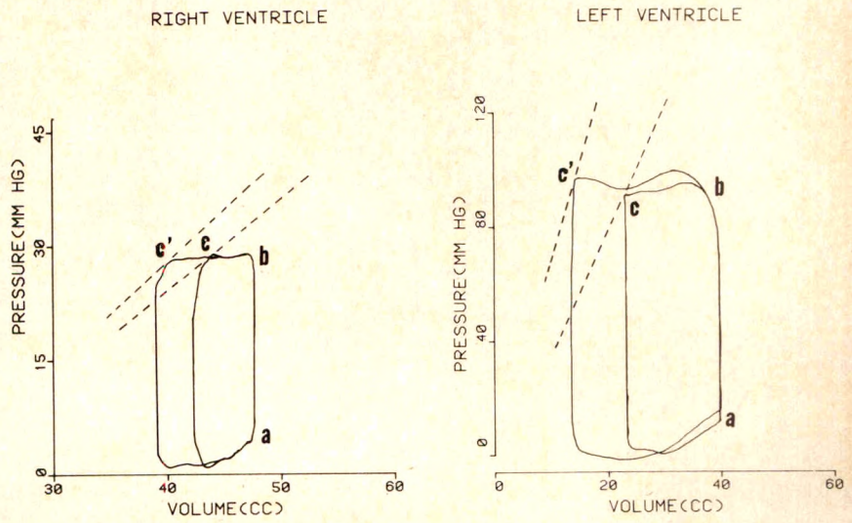

FIGURE 4. The interrelation between the isovolumetric pressure-volume relation and an ejecting contraction. Shown are end-diastolic (a), onset (b) and end-ejection (c) values before and after the increment in myocardial contractile state (dobutamine, 6 μg/min). End-ejection pressure and the extent of ejection (that is, stroke volume) are related to the isovolumetric maximal pressure-volume relations. An increase in stroke volume occurs with dobutamine because the ventricle can now eject to a greater extent (to point c′).

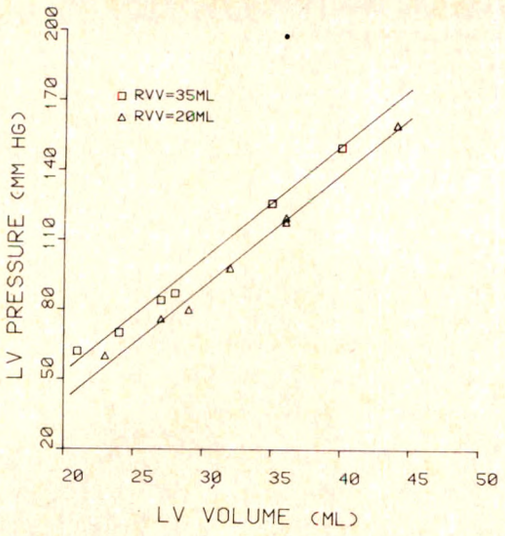

FIGURE 5. A parallel shift in the isovolumetric pressure-volume relation of the left ventricle (LV) occurs when the volume of the right ventricle (RVV) increases from 20 to 35 ml.

ventricle twice normal size may have a stroke volume that only approximates the output of the normal heart because the contractile state is concomitantly reduced.

The contractile mechanics of the myocardium describe the pumping behavior of the right and left ventricles. Up to this point, the importance of preload, afterload and myocardial contractile state have been emphasized in regulating the performance of the muscular pump. The mechanical interaction between ventricles created by the interventricular septum, pericardium and variations in pleural pressure also determine the size, shape and load of the ventricles. These factors are particularly important when one is considering cardiac performance in the patient who has respiratory failure.

Interaction of the Right and Left Ventricles

As noted earlier, the myocardium is composed of muscle fibers tethered within a supportive network of collagen. Recent observations from this laboratory[8a] indicate that the muscle fiber alignment of the interventricular septum resembles that of the left ventricular free wall. Hence, on morphologic grounds the septum can be considered part of the left ventricle. However, because the right and left ventricles are aligned in series and mechanically coupled, a perturbation in the mechanical events of one ventricle will influence the behavior of the other ventricle, and in nonsteady state conditions the output of the two ventricles may not be balanced. Eventually, however, a steady state of balanced outputs must occur if pulmonary or systemic venous congestion is to be avoided.

To discern the relative contribution of the septum, pericardium and pleural pressure to the mechanical interaction of the ventricles, it is necessary either to segregate each component while maintaining the heart intact or to monitor carefully the physiologic behavior of each component with the chest intact. We have chosen the former approach using an isolated canine heart.

The Direct Interaction Between Ventricles

Diastolic interplay between ventricles: With our isolated heart preparation the volume in each ventricle can be controlled.[9] Hence, it is possible to assess the pressure-volume relation of one ventricle while the filling volume in the other ventricle is varied. Figure 7 shows a typical response, with and without the pericardium. It can be seen that for any constant volume of the right ventricle (15, 34 or 39 cc, upper right panel), this chamber's filling pressure increased nonlinearly as the volume of the left ventricle was progressively increased over the filling pressure range of 0 to 20 mm Hg. The diastolic interplay between ventricles was more pronounced the greater the volume of the right ventricle. A similar response in left ventricular diastolic pressure was observed as right ventricular volume was increased over the same range in filling pressure (lower right panel, Fig. 7). The change in diastolic pressure that occurred in each ventricle was quite similar in 15 hearts examined and ranged from 1 to 3.5 mm Hg in the right ventricle and 0.7 to 4.9 in the left ventricle.[7]

Systolic interplay between ventricles: During systole the pressure in one ventricle will also influence the systolic pressure developed in the other. The systolic

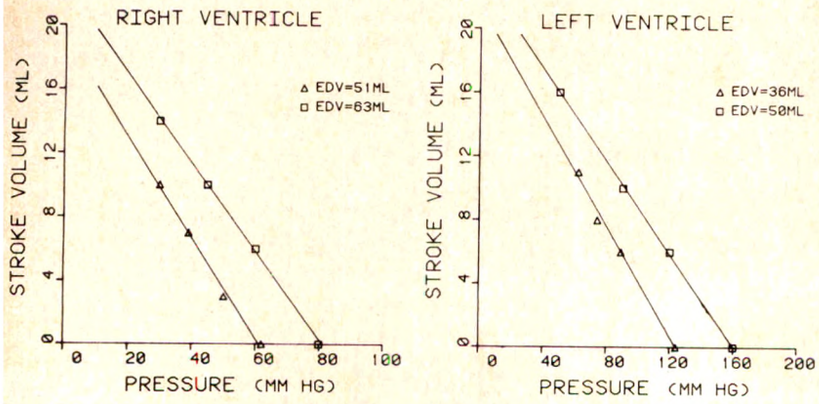

FIGURE 6. An inverse relation exists between stroke volume and ejection pressure in either ventricle. The greater the end-diastolic volume (EDV) of the ventricle the greater its stroke volume for any given ejection pressure.

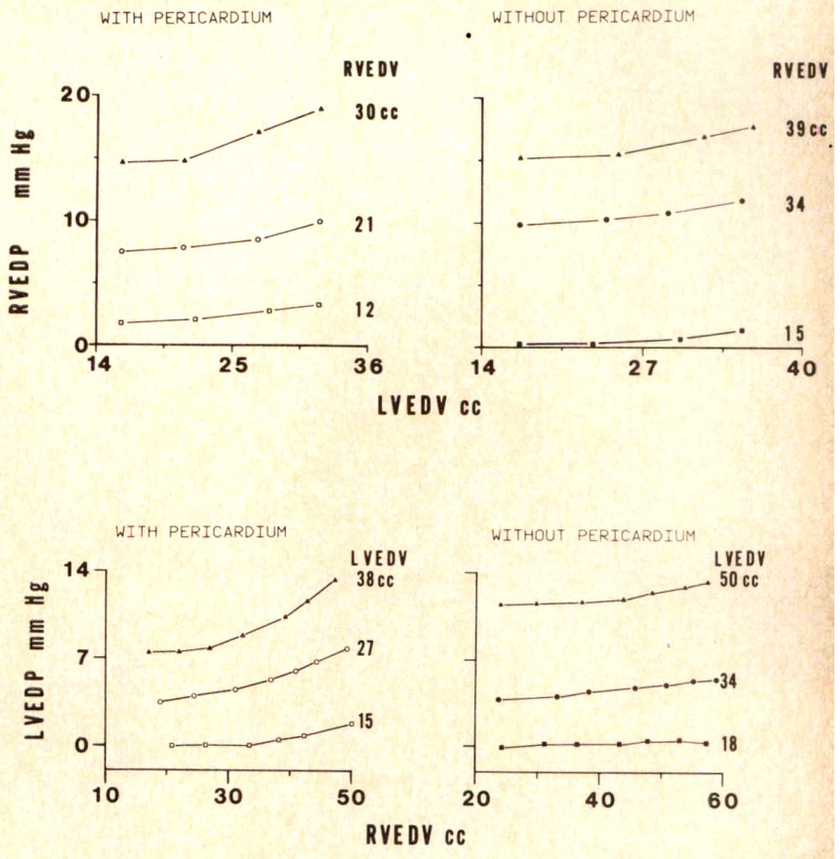

FIGURE 7. The diastolic interaction between ventricles in the absence of the pericardium is demonstrated in the **right panels.** The pericardium serves to accentuate this interaction (**left panels**). LVEDP and RVEDP = left and right ventricular end-diastolic pressure, respectively; LVEDV and RVEDV = left and right ventricular end-diastolic volume, respectively. Modified from Janicki and Weber[7] with permission of the *American Journal of Physiology*.

interplay between ventricles particularly applies to the influence that the left ventricle exerts on right ventricular pressure development. For example, Figure 8 shows that the systolic pressure of the isovolumetrically beating right ventricle became greater as left ventricular systolic pressure increased. The slope of each relation was quite similar, indicating that for any volume, the right ventricle was equally sensitive to left ventricular systolic pressure. The influence of right ventricular systolic pressure on left ventricular pressure is only apparent when the pressure generated by the left ventricle is markedly reduced to hypotensive levels and comparable with right ventricular systolic pressure. Hence, this interplay is minimal under normal physiologic conditions.

Interventricular septum: As several investigators[10–15] have previously demonstrated, the interaction between ventricles during diastole and systole reflects the importance of the interventricular septum and its position. When the transseptal force gradient favors a rightward shift of the septum, as in acute left ventricular distension (Fig. 2), diastolic pressure in the right ventricle either increases or remains invariant despite a reduction in chamber volume. The reverse is also true for the left ventricle. The septal surface forces also serve to buttress the septum during systole and retard its motion so that the pressure developed by either ventricle becomes greater. The influence of right ventricular volume on the maximal pressure-volume relation of the isovolumetrically beating left ventricle is depicted in Figure 5. As right heart volume is increased, a parallel leftward shift of the left ventricular pressure-volume relation occurs. The relative importance of septal motion to ventricular interaction and pump function was also evident in the classic experiments of Starr,[14] who found that central venous pressure and cardiac output remained normal after massive destruction of the canine right ventricular free wall. In contrast, right heart performance deteriorates when right ventricular infarction occurs in the presence of an infarcted septum.[15,16]

The Pericardium and Ventricular Interaction

The pericardium surrounds the atria and ventricles, and its viscoelastic properties impose a physical constraint on acute cardiac distension.[7] As one would expect from its curvilinear pressure-volume relation, the pericardium exerts its predominant influence at larger cardiac volumes. After pericardiectomy the greatest reduction in filling pressure in either ventricle occurs at larger filling volumes. Over the range of filling pressures examined (0 to 20 mm Hg) the average upward shift in end-diastolic pressure of the right and left ventricles due to the pericardium was identical (mean ± standard error of the mean +4.3 ± 0.6 and +4.6 ± 1.0 mm Hg, respectively).

Because filling pressure is reduced in either ventricle after pericardiectomy, although ventricular volume is held constant, the distending force (pressure and di-

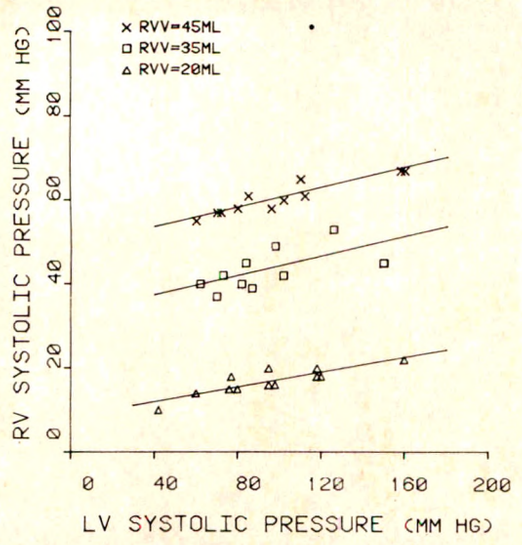

FIGURE 8. Left ventricular systolic pressure development contributes to the pressure generated by the right ventricle (RV). The extent of this interaction appears to be equivalent for several right ventricular diastolic volumes (RVV).

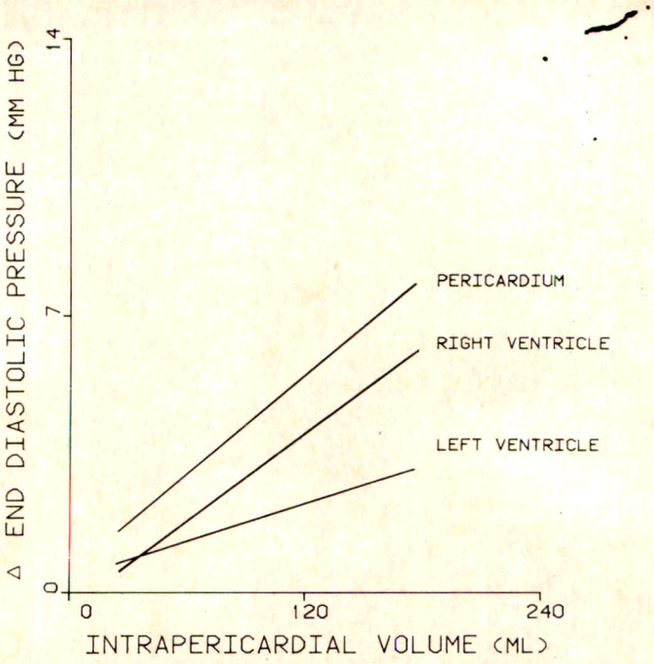

FIGURE 9. The changes (Δ) in end-diastolic pressure for the pericardium (PEDP) and right (RVEDP) and left (LVEDP) ventricles are shown as a function of intrapericardial volume. As pericardial volume increases the external pressure on the ventricles also increases, augmenting their diastolic pressure and reducing the effective compliance of the chambers. Modified with permission.

mension), or preload, on the myocardium is also reduced. Commensurately, the developed systolic pressure will decrease after removal of the pericardium. This effect was also similar in both the right and left ventricles (−5.8 ± 2.2 and −4.1 ± 2.0 mm Hg, respectively).

By imposing a physical constraint on the expansion of either ventricle, the pericardium enhances the degree of ventricular interaction (left panels, Fig. 7). These responses can be compared with those that occur when the pericardium is absent (right panels, Fig. 7). In the presence of the pericardium the change in diastolic pressure caused by ventricular interaction (filling pressure range 0 to 20 mm Hg) ranged from 1.3 to 5.6 mm Hg in the right and from 1.4 to 11.0 mm Hg in the left ventricle. However, the degree of systolic interaction after pericardiectomy was more variable. Normally the mechanical influence of the pericardium during systole is minimal as cardiac volume declines.

Transmural Pressure

The heart is surrounded by the pericardium and situated in the thorax. The pressures inside the pericardial sac and intrathoracic cavity determine the pressure exerted on, or external to, the heart. Intrapericardial and intrathoracic pressures are normally quite similar and range from −3 mm Hg at end-expiration to −6 mm Hg with inspiration.[17] The degree of negative intrathoracic pressure can be increased dramatically with the augmented inspiratory effort associated with acute bronchospasm (resistive loading) or a Müller maneuver (that is, forced inspiration against a closed glottis). On the other hand, a Valsalva maneuver, pneumothorax, mechanical ventilator or conditions of positive expiratory pressure serve to create a positive intrathoracic pressure.

In considering the influence of pleural pressure on the heart, and specifically its ventricles, it is best to speak in terms of the transmural pressure (that is, the difference in pressure across the myocardium or between the inside and outside of the ventricle).[18] For either ventricle, transmural pressure describes its effective filling pressure; the transmural pressure of the pulmonary artery or aorta indicates the pressure that opposes ventricular ejection. Because ventricular volume is subject to change, transmural ventricular diastolic pressure is increased with negative intrathoracic pressure and decreased when the pressure within the pleural space becomes positive. In addition to the influence of transmural pressure on ventricular filling, the venous return to the right heart chambers is dependent on the gradient in pressure between the extra- and intrathoracic veins. Positive intrathoracic pressure reduces this gradient, whereas negative pressure raises the gradient favoring venous return. For example, if this gradient were 5 mm Hg, a 5 mm Hg reduction in pleural pressure would increase this gradient to 10 mm Hg.

Reducing transmural pressure: To isolate the influence of a positive external pressure (that is, reduced transmural pressure) on the behavior of the ventricles and their interaction without the influence of alterations in lung volume, we monitored the responses of right and left ventricular pressure to increasing levels of intrapericardial pressure in the open chest dog in which ventricular volumes were free to change (Fig. 9).[18a]

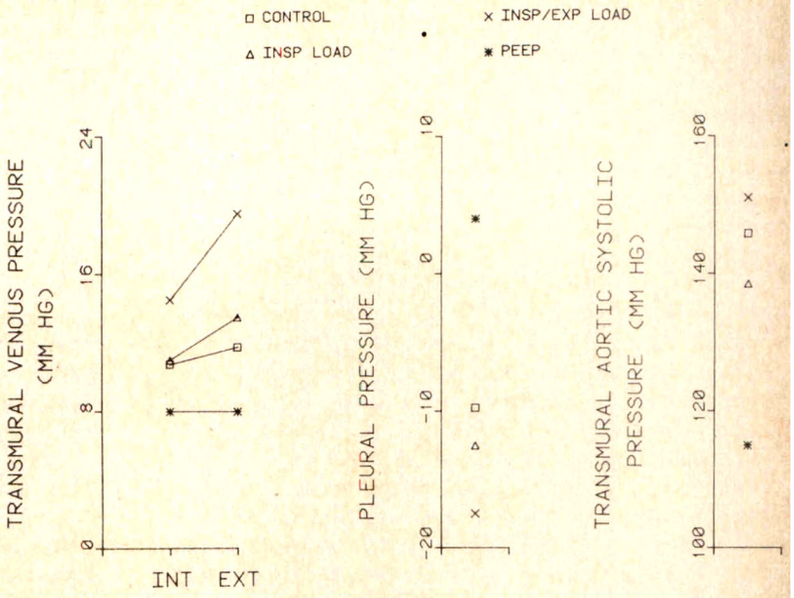

FIGURE 10. Intra- (INT) and extrathoracic (EXT) venous pressures were measured and referenced to pleural pressure, the difference being transmural venous pressure. The alteration in transmural venous and aortic pressures that occur during negative and positive variations in pleural pressure are presented for the following conditions: (1) control (spontaneous respirations in an intubated, anesthetized dog breathing through a Hans-Rudolph valve); (2) inspiratory (INSP) load (a narrowing [2 mm orifice] of the inspiratory port of the valve); (3) inspiratory/expiratory (INSP/EXP) load (2 mm orifice at the endotracheal tube); and (4) positive end-expiratory pressure (PEEP) (15 cm H_2O positive end-expiratory pressure during assisted ventilation). The difference between extra- and intramural venous pressure equals the venous filling gradient to the right heart chambers.

The average increase in pericardial and ventricular end-diastolic pressures are given as a function of pericardial volume in Figure 9. These responses in pericardial and ventricular pressure to a pericardial effusion were calculated by subtracting the initial level of pressure in the pericardium and the right and left ventricles from the corresponding pressures observed during tamponade. The amount by which each pressure increased during tamponade differed; the increase in pressure in the pericardium was greatest, whereas that in the left ventricle was least. In fact, when left ventricular end-diastolic pressure was 12 mm Hg or more at the onset of the infusion, left ventricular pressure actually decreased as pericardial volume increased. Thus, the increase in filling pressure in the right ventricle was greater than that in the left ventricle and, in all likelihood, represents the difference in distensibility between ventricles; that is, the stiffer left ventricle will have a larger decrease in diastolic pressure for any given reduction in its volume. Accordingly, with increments in external pressure its filling pressure changes less, or may even decrease, in comparison with the response in pressure in the more distensible right ventricle. Hence, even though a diastolic pressure in the two ventricles may be 15 mm Hg with a chronic pericardial effusion the difference in ventricular distensibility may account for the greater decrement in filling pressure in the right as compared with the left ventricle after pericardiocentesis.[19]

Because the effective ventricular filling pressure is the transmural diastolic pressure of the ventricle, it is clear from Figure 9 that during tamponade the transmural pressure for both ventricles was decreasing as pericardial pressure increased. However, because the increase in end-diastolic pressure in the left ventricle was less than that in the right ventricle the transmural pressure declined by a lesser amount in the right ventricle. Thus, the ability of either ventricle to maintain its effective filling pressure during tamponade depends on the increase in filling pressure with respect to the increase in pericardial pressure. Similarly, the preservation of the filling pressure gradient to the right atrium during tamponade or any increase in extracardiac pressure, such as positive expiratory pressure (Fig. 10), is dependent on a compensatory increase in peripheral venous tone to maintain venous return.

Transmural pressure is also reduced when intrathoracic pressure is increased during the strain phase of a Valsalva maneuver or with mechanical ventilation. The extent to which intrathoracic pressure increases is dependent on the compliance of the chest wall and lungs, lung volume, time in which the lungs are held in the inflated state and the extent to which airway pressures are transmitted to the intrathoracic vessels. During the strain phase of a Valsalva maneuver, Brooker[20] and Buda[21] and their co-workers found that both end-diastolic and end-systolic volumes as well as cardiac output decreased, as one would expect with a reduction in transmural ventricular pressure and a decrease in the venous gradient. However, transmural pressure in the intrathoracic aorta would decrease during the Valsalva maneuver.[20,21] On the basis of our knowledge of the behavior of the muscle pump, this reduction in transmural aortic pressure would favor an increase in stroke volume. This effect is obviously offset by the greater decrease in ventricular transmural pressure and the end result is a decrease in stroke volume.

Intermittent and continuous positive pressure ventilation are used to increase arterial partial pressure of oxygen in patients with acute respiratory failure. Although arterial partial pressure of oxygen may be increased with assisted ventilation, cardiac output often decreases as pleural pressure is increased, com-

promising oxygen delivery. The mechanisms that account for the decrease in cardiac output are not fully understood. However, the following physiologic consequences of positive pleural pressure are certainly operative. Transmural ventricular pressure and the venous gradient across the thorax decrease during positive pressure ventilation (Fig. 10). As a result, venous return and right ventricular diastolic volume and output are attenuated.[22] If the effective distensibility of the right ventricular chamber were also reduced by positive intrathoracic pressure (analogous to a pericardial effusion) this would further contribute to a reduction in the filling volume of this chamber, even though filling pressure may not decrease.[23,24] The same would also apply to left ventricular distensibility,[25] which also would tend to minimize the change in filling pressure. Although transmural pulmonary arterial pressure should be less, the positive pleural pressure contributes a compressive force to the pulmonary vasculature and may serve to elevate pulmonary vascular resistance depending on the functional residual capacity. The impedance characteristics of the pulmonary circulation would also be distorted by the mechanical ventilation and the duration of each inflation. The fact that transmural pulmonary arterial pressure actually increases in the presence of diminished right heart output[26] lends support to this interpretation and may also contribute to the preservation or elevation in filling pressure, and perhaps even increase right ventricular diastolic volume.[24] Hence, there are a variety of purely mechanical explanations favoring reduction in cardiac output on the basis of reduction in right ventricular output and diminished left ventricular filling.

In contrast, other investigations[23,24,26] have considered this decrease in cardiac output the result of indirect mechanisms, including a depression in myocardial blood flow, circulating vasoactive substances released from the lung, reflex cardiovascular depression accompanying lung inflation, and the activation of neural receptors within the lung. The actual mechanism that accounts for the decrease in cardiac output with positive pressure ventilation, whether mechanical or indirect, requires further investigation.

Increasing transmural pressure: Intrathoracic pressure can be reduced substantially during a Müller maneuver (that is, an inspiratory load) or with the forced inspiratory and expiratory effort associated with marked airway resistance (that is, acute bronchospasm or chronic obstructive airway disease). As a result, the transmural ventricular filling pressure and the venous gradient to filling both increase, favoring an enhanced venous return (Fig. 10) and an increase in right ventricular volume. However, the increase in venous return is not proportional to the decrease in pleural pressure because the extrathoracic veins are collapsible. The greater the central venous pressure (as in cor pulmonale, biventricular failure or pericardial effusion) the greater the venous return for any given decrease in intrathoracic pressure.

The increase in right ventricular filling volume and pressure alters the transseptal force gradient, promoting a flattening and leftward shift of the septum that reduces the size of the left ventricular chamber and alters its shape (Fig. 2). As a consequence, the effective compliance of the left ventricular chamber is reduced as is its filling volume. Together the reduction in filling volume and elevation of aortic transmural pressure[27,28] account for the decrease in left ventricular stroke volume and the resultant decrease (less than 10 mm Hg) in arterial pressure that normally accompanies inspiration. More marked reductions in pleural pressure accentuate this disequilibrium and account for the "paradoxical" pulse observed in the patient with acute asthma.

With cardiac dilatation the pericardium will accentuate the increase in right ventricular filling pressure and the encroachment of the septum within the left ventricle when intrathoracic pressure becomes more negative. Changes in left ventricular geometry and distensibility may also account for the relative impairment in left ventricular pump function noted in patients with chronic airway disease.[29] Similarly, the association of mitral valve prolapse with atrial septal defect may be the result of altered left ventricular geometry and the leftward position of the interventricular septum with chronic right heart distension.[30]

Control of Cardiac Output by Systemic Vessels

Circulatory Adjustments to Acute and Chronic Respiratory Failure And the Effect of Therapeutic Interventions

HOWARD S. GOLDBERG, MD*
JOHN RABSON, MD†

Winnipeg, Manitoba, Canada

The circulation requires the heart to pump blood from the venous to the arterial bed. The factors that determine venous flow into the heart are mean pressure in the systemic vasculature, right atrial pressure and the resistance to venous return. The mean pressure in the systemic vasculature is a function of the stressed vascular volume and the systemic vascular compliance. Right atrial pressure depends on many factors. These include the contractile state of the right and left ventricles, the load on the right and left ventricles, the presence or absence of pericardial effusion, and alterations in pleural pressure that might occur with positive pressure ventilation. The resistance to venous return tends to stay remarkably constant, but can be reduced by significant arteriovenous shunting.

The right ventricle has a relatively high diastolic compliance. Because of this, changes in volume of the right ventricle are associated with only modest increases in right atrial pressure. Therefore, as load on the right ventricle increases, mean systemic vascular pressure needs to increase only a small amount to maintain cardiac output. If right atrial pressure increases sufficiently as a result of a greatly increased load on the right ventricle, as in pulmonary embolism, hypoxic pulmonary vasoconstriction or chronic respiratory failure, the increase in mean systemic vascular pressure necessary to maintain normal venous return, and therefore cardiac output, may lead to signs of right heart failure, with no change in the slope of the right heart function curves. The implications of this phenomenon are important in managing patients with acute and chronic respiratory failure. Positive pressure ventilation, diuretic agents, cardiac glycosides and other inotropic or vasoactive drugs will influence the relation between the mean systemic pressure and right atrial pressure. Therefore, these treatment modalities may unexpectedly alter cardiac output if the systemic vascular effects are not kept in mind.

This review presents an integrated approach to circulatory function based on the factors that influence venous return. The circulatory adjustments to acute and chronic respiratory failure and the effect of various therapeutic interventions on venous return are discussed as well. With an understanding of the systemic vascular mechanics that influence venous return, and therefore cardiac output, circulatory derangement in patients treated for respiratory failure can be better managed.

Cardiac output depends on a functioning heart and on the amount of blood presented to the heart to be pumped out. Thus, the heart can be conceptualized as a pump in a closed loop circuit of elastic tubes (Fig. 1). The central compartment is portrayed in a single box. For the purposes of this review, this compartment is of interest because the downstream pressure for the entire circulation can be thought of as the right atrial pressure. Even from this schematic representation, it is obvious that right atrial pressure is contingent upon the interdependent relation of the right heart chambers with the lungs, the left heart chambers and the surrounding pressures of all these structures.

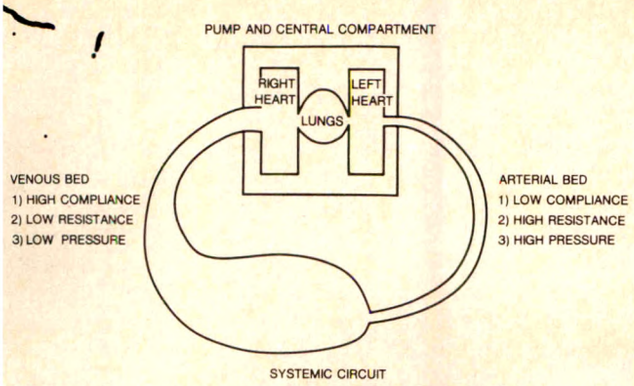

FIGURE 1. Schematic diagram of the circulatory system.

The systemic circuit in Figure 1 consists of an arterial side and a venous side in series. The arterial portion of the circuit has a low compliance and a high resistance to flow; the venous side has a high compliance and a low resistance to flow. In the dog, arterial compliance is about 1/20 that of venous compliance, and arterial resistance is about 20 times venous resistance.[1] Under ordinary flow conditions, arterial pressure is about 10 times greater than venous pressure. However, if the circulation were stopped and allowed to come to equilibrium, the pressure everywhere in the circulatory system at any given hydrostatic level would be the same. This pressure has been termed mean systemic pressure by Weber, as cited by Starling.[2]

Mean Systemic Pressure

Mean systemic pressure is determined by vascular compliance and the stressed volume in the vascular bed.

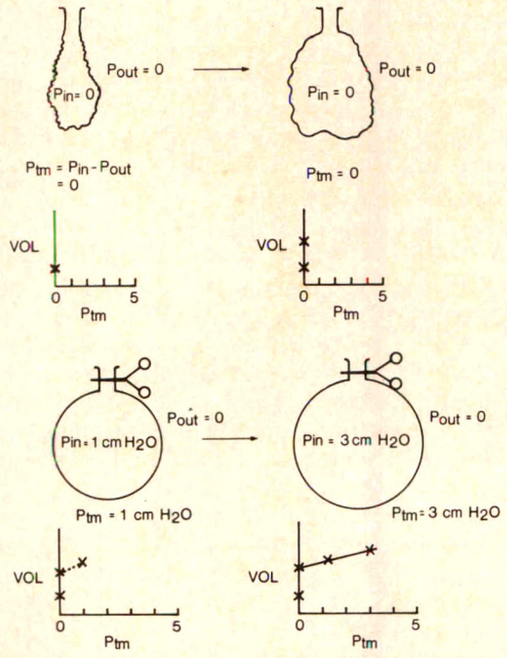

FIGURE 2. An example demonstrating the concept of unstressed volume. P_{in} = pressure inside the large floppy balloon; P_{out} = pressure outside the large floppy balloon; P_{tm} = transmural pressure; VOL = volume within the balloon.

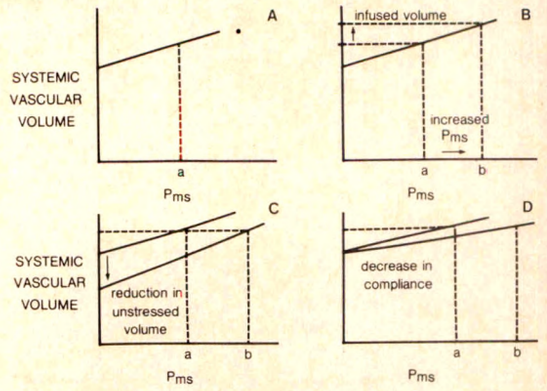

FIGURE 3. Mean systemic pressure (P_{ms}) can be increased by the addition of stressed volume to the systemic vascular circuit (**A**). This can occur in three ways. **B,** one way is an infusion of volume into the systemic vasculature. **C,** another way is a reduction in the unstressed volume of the vasculature at constant intravascular volume, which could occur with vasomotor reflexes. **D,** another method for increasing P_{ms} at a constant vascular volume is by a decrease in systemic vascular compliance.

Stressed volume is the volume associated with a positive change in transmural pressure. Unstressed volume is the volume in an elastic container that is *not* associated with a positive transmural pressure. Consider a large, floppy bag open to atmosphere (Fig. 2). The pressures inside and outside the bag are atmospheric. If some volume is added to the bag but the top is kept open to atmosphere, the pressure inside the bag is still zero and the transmural pressure is still zero. As more volume is added to the bag, there will be a point at which the top must be sealed because the pressure inside the bag will be greater than atmospheric pressure. This is the unstressed volume. The transmural pressure increases with the addition of more volume to the sealed bag. The slope of a line connecting the pressure volume points is the compliance of the bag. Changing the axes to represent mean systemic pressure on the abscissa and systemic vascular volume on the ordinate (Fig. 3) demonstrates that mean systemic pressure is a simple function of vascular stressed volume and vascular compliance.

Vascular Pressure and Volume Distribution With Flow

With the circulation completely stopped and the pressure equilibrated, if the heart begins to beat, blood is pumped from the venous side of the circulation into the arterial side. Because the arterial bed has a relatively high resistance to flow, not all of the blood added to the arterial side drains out before the next beat. As each succeeding beat increases the volume in the arterial bed, pressure will continue to increase until it is high enough to allow all the stroke volume to drain across the arterial resistance into the venous bed. The pressure in the arterial bed increases with the added volume as a function of its compliance. Because arterial compliance is low, a small amount of blood added to the arterial side causes a relatively large increase in arterial pressure. In this circuit (Fig. 1), the blood added to the arterial side comes at the expense of the volume in the venous bed.

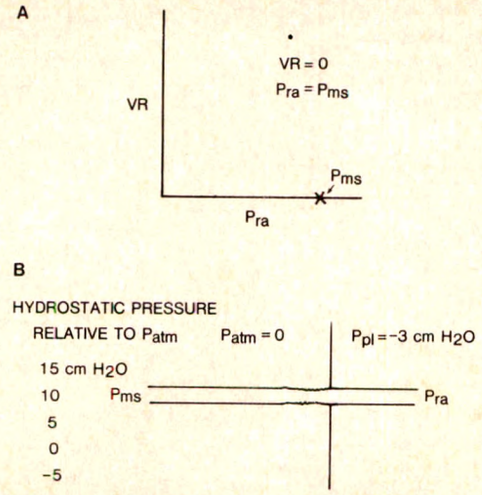

FIGURE 4. A, when there is no flow in the circulatory system, there is no venous return (VR), and pressure in the right atrium (P_{ra}) is equal to the mean systemic pressure (P_{ms}). **B,** a model of the circulation with no flow. The scale on the **left** shows that mean systemic pressure and right atrial pressure are both equal to 10 cm H_2O relative to atmospheric pressure (P_{atm}). Therefore, there is no flow. Note that the transmural right atrial pressure would be 13 cm H_2O.

Because the compliance of this bed is very high, a shift of volume out is associated with only a small change in venous pressure.

When the heart starts to beat, it increases the pressure on its outflow side by adding volume to the systemic circuit from the central compartment. As the left heart chambers are refilled from the right heart chambers, the volume and, concurrently, the pressure are reduced in the right side of the heart. With a reduced pressure in the right atrium, the inflow side of the heart, blood flows from the circuit to the pump.

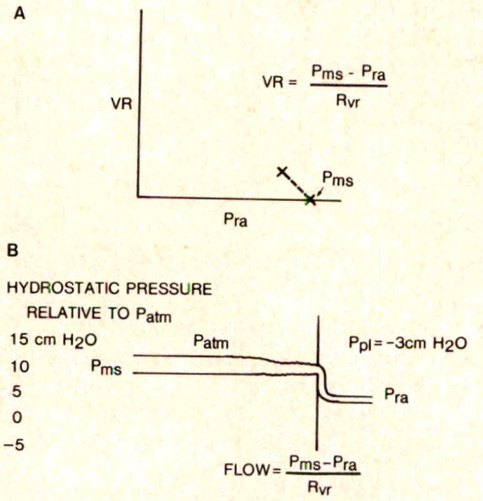

FIGURE 5. A, when right atrial pressure (P_{ra}) is reduced at a given mean systemic pressure (P_{ms}), venous return (VR) is determined by the difference between mean systemic and right atrial pressure divided by the resistance to venous return (R_{vr}), which is the reciprocal of the slope of the line. **B,** a model of the circulation with flow and right atrial pressure greater than atmospheric pressure (P_{atm}). The scale on the **left** shows that mean systemic pressure is unchanged and is still 10 cm H_2O. Right atrial pressure is now 5 cm H_2O. The pressure gradient for flow is mean systemic pressure minus right atrial pressure; this is 5 cm H_2O. Note that transmural right atrial pressure is 8 cm H_2O.

For the purposes of this discussion, we will assume that outflow and inflow are equal, a reasonable assumption in a steady state. With this condition, it is obvious that vascular stressed volume has not changed, although the pressures around the circuit have changed; arterial pressure is increased a great deal, and venous pressure is reduced a small amount. Because the stressed volume in the circuit has not changed but is merely redistributed, to calculate mean systemic pressure during flow one would have to know the pressure in each segment of the circuit and weigh that pressure as a function of compliance of the segment, as a fraction of total systemic compliance. If total systemic compliance is unchanged, then mean systemic pressure during flow is the same as when there is no flow.

Determinants of Venous Return

Right Atrial Pressure

The amount of venous return and, therefore of steady state cardiac output, is proportional to the difference between mean systemic pressure and right atrial pressure. However, for any mean systemic pressure there is a limit to how much venous return can occur as right atrial pressure is reduced. If the latter is sufficiently reduced, the inflow veins will undergo a decrease in pressure. If this pressure becomes less than the surrounding pressure, the veins will collapse.[3,4] This is analogous to the situation in the lung where inflow pressure or pulmonary arterial pressure is greater than alveolar pressure, but alveolar pressure is greater than outflow pressure or pulmonary venous pressure. This is the zone II described by West et al.[5] The driving pressure for flow is pulmonary arterial pressure minus alveolar pressure; reducing pulmonary venous pressure does not influence flow. Indeed, the vessels exposed to alveolar pressure in zone II behave like Starling resistors, which limit flow as downstream pressure is reduced.[5] In this analogy, mean systemic pressure is equivalent to pulmonary arterial pressure, right atrial pressure is equivalent to pulmonary venous pressure, and atmospheric pressure is equivalent to alveolar pressure. Therefore, lowering right atrial pressure below the surrounding pressure of the collapsible veins will not influence venous return. Graphically, these concepts are represented in Figures 4 to 6. At zero venous return (Fig. 4A), that is, at no flow in the system, the pressure everywhere in the system is the same and equal to mean systemic pressure. Therefore, right atrial pressure at zero flow is equal to mean systemic pressure. This condition is shown in a model in Figure 4B.

If right atrial pressure is lowered by starting the pump (Fig. 5A), mean systemic pressure does not change, but a pressure gradient for venous return is created. The amount of venous return is proportional to the difference between mean systemic and right atrial pressures and is inversely related to the resistance to venous return. The slope of the line connecting the two points is the reciprocal of this resistance. Figure 5B shows the

relation in terms of our model: Right atrial pressure is lower than mean systemic pressure but is greater than atmospheric pressure, the pressure surrounding the collapsible veins. As right atrial pressure is further lowered with the volume in the circuit unchanged, venous return continues to increase (Fig. 6A). As right atrial pressure falls below the pressure surrounding the veins entering the thoracic cavity, they tend to collapse and limit venous return. In Figure 6B, right atrial pressure is lower than the pressure surrounding the collapsible veins, causing them to collapse and limit flow. To complete the zone II of the analogy of West et al.,[6] right atrial pressure is equivalent to pulmonary venous pressure, atmospheric pressure is equivalent to alveolar pressure and mean systemic pressure is equivalent to pulmonary arterial pressure.

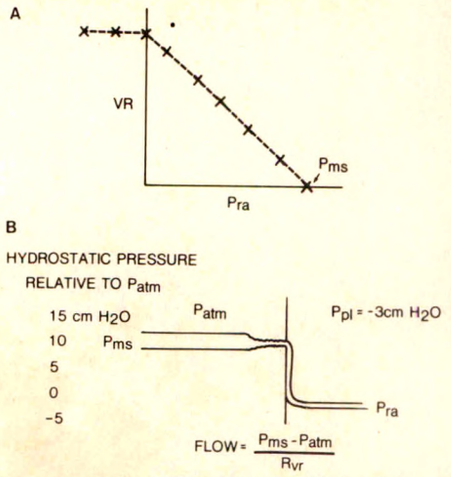

FIGURE 6. A, as pressure in the right atrium (P_{ra}) is reduced more and more at a given mean systemic pressure (P_{ms}), venous return (VR) continues to increase until right atrial pressure decreases below a certain value. Once right atrial pressure reaches a low enough value, the pressure in the veins entering the thorax falls below the pressure surrounding them, and they collapse. The surrounding pressure of the veins is then the pertinent back pressure in determining flow. **B,** a model of the circulation with right atrial pressure below the pressure surrounding the collapsible veins. In this example that pressure is atmospheric (P_{atm}). The scale on the **left** shows that mean systemic pressure is still 10 cm H_2O. Right atrial pressure is −2 cm H_2O. Therefore, the pressure gradient for flow is mean systemic pressure minus atmospheric pressure. This is 10 cm H_2O. A further decrease in right atrial pressure will not influence the flow. Note that transmural right atrial pressure is 1 cm H_2O.

Resistance to Venous Return

Further lowering of right atrial pressure does not increase venous return. However, venous return can be increased if mean systemic pressure is increased (Fig. 7B) or if the resistance to venous return is decreased (Fig. 7A). The resistance to venous return is an average of all the regional resistances from the systemic circuit back to the right atrium. Each regional resistance is weighted by its contribution to the entire systemic vascular compliance and the fraction of the cardiac output draining from each region.[1] As a practical matter, it is known that the resistance to venous return remains remarkably constant under a wide variety of circumstances, increasing only slightly with large adrenergic stimulation.[1,6] A clinically important effect of a reduced resistance to venous return is arteriovenous shunting. This reduces the resistance to venous return and allows an increase in cardiac output with no change in mean systemic or right atrial pressure[7] (Fig. 7A). Hypoxia, exercise or even redistribution of cardiac output by nonuniform changes in arterial resistance can also alter the resistance to venous return. Because alterations in resistance to venous return in respiratory failure have not been studied to any great extent, changes in mean systemic pressure currently have greater clinical importance.

Mean Systemic Pressure

Maintaining adequate cardiac output is particularly important in patients with increased pressures in the right side of the heart. Increased pressure may be a result of left heart failure, chronic obstructive pulmonary disease, pulmonary emboli or hypoxic vasoconstriction. Positive pressure ventilation, especially with added positive end-expiratory pressure, also will cause right atrial pressure to increase in relation to atmospheric pressure even though transmural right atrial pressure may have decreased. Clearly, if right atrial pressure increases in relation to atmospheric pressure, mean systemic pressure must increase just as much if normal venous return, and therefore cardiac output, is to be maintained.

Mean systemic pressure can be changed by adding volume to the circuit (Fig. 3A). This can come by infusion, but anything that increases the stressed volume of the circuit will have the same effect. Figure 3B shows that infusion of volume increases mean systemic pressure as a function of vascular bed compliance. However, with no change in vascular volume, mean systemic pressure can be increased by decreasing the unstressed volume (Fig. 3C). This can result from contraction of the muscles in the walls of the vascular bed, as occurs reflexly when there is blood loss. With no change in vascular volume, decreasing the vascular compliance itself will result in an increase in mean systemic pressure, as well (Fig. 3D).

Another way mean systemic pressure can be increased is by translocation of blood from the central compartment to the systemic circuit.[8] The net effect

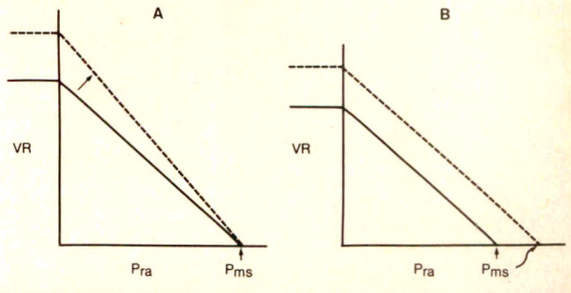

FIGURE 7. Two ways venous return (VR) can be increased are depicted. **A,** one way is for resistance to venous return to decrease. **B,** another way is for mean systemic pressure (P_{ms}) to be increased with resistance to venous return unchanged. P_{ra} = right atrial pressure.

of this is to decrease right atrial pressure and, by adding stressed volume to the systemic circuit, to increase mean systemic pressure. This can occur if the heart has either an improvement in inotropic state at a constant afterload or a reduction in afterload. Therefore, under conditions of acute or chronic increases in right heart pressure, the body has several mechanisms available to increase venous return. And, in a steady state, no matter how excellent cardiac function, the heart can pump out only what is returned.

The Cardiac Function Curve

For a given stressed vascular volume and systemic vascular compliance, mean systemic pressure is set, and the resistance to venous return can be considered relatively constant. Therefore, in the absence of pulmonary hypertension or right heart dysfunction, left ventricular function will ultimately determine right atrial pressure and therefore venous return. Of course, this is limited by the Starling resistor effect, described earlier.

In Figure 8A a venous return curve is plotted with a simultaneous cardiac function curve. It can be seen that cardiac output is uniquely determined by the intersection of the two curves. It should be remembered that the cardiac function curve relates cardiac output to all of the factors in the central compartment that can influence right atrial pressure. These factors include left and right heart passive tension curves, the pericardium, the load on the left and right ventricles, mechanical interaction between the lung and the heart, and pleural pressure. The interdependence of these factors is discussed elsewhere in this Seminar.[9]

A cardiac function curve can be determined by observing the effect on cardiac output of increasing the filling of the right atrium. As the right atrium is filled, its transmural pressure increases as a function of its compliance. Heretofore, we have considered only the value of right atrial pressure in relation to atmospheric pressure. If the local pleural pressure acting on the outside of the intact right atrium is assumed to be -3 cm H_2O, we can subtract 3 cm H_2O from the transmural right atrial pressure and obtain a right atrial pressure value relative to atmosphere in the intact system.

In practical terms, the cardiac function curve is obtained by the addition of volume to the heart at a single output load. This is done by increasing mean systemic pressure in steps (Fig. 8B). The cardiac output and right atrial pressure are determined at each of the several levels of mean systemic pressure. The increase in pressure in the right atrium is linked to all of the aforementioned factors. For example, patients on positive pressure ventilation or positive end-expiratory pressure have a higher right atrial pressure in relation to atmosphere at the same transmural right atrial pressure (Fig. 8C). This analysis assumes no change in the cardiac function curve as a result of increased pleural pressure, and mean systemic pressure would have to be increased an equal amount to maintain cardiac output. Figure 8D demonstrates that without the increase in mean systemic pressure, cardiac output would be reduced substantially.

Increased output load on the right heart chamber necessitates greater pressure in these chambers to maintain the flow of blood from the right to the left side. As this pressure increases, the volume in the right heart chambers, and therefore mean transmural right atrial pressure, increases. The pressure-volume relation of the right atrium has not been determined, but a diastolic pressure-volume curve for the canine right ventricle has been measured.[10,11] In Figure 9 the

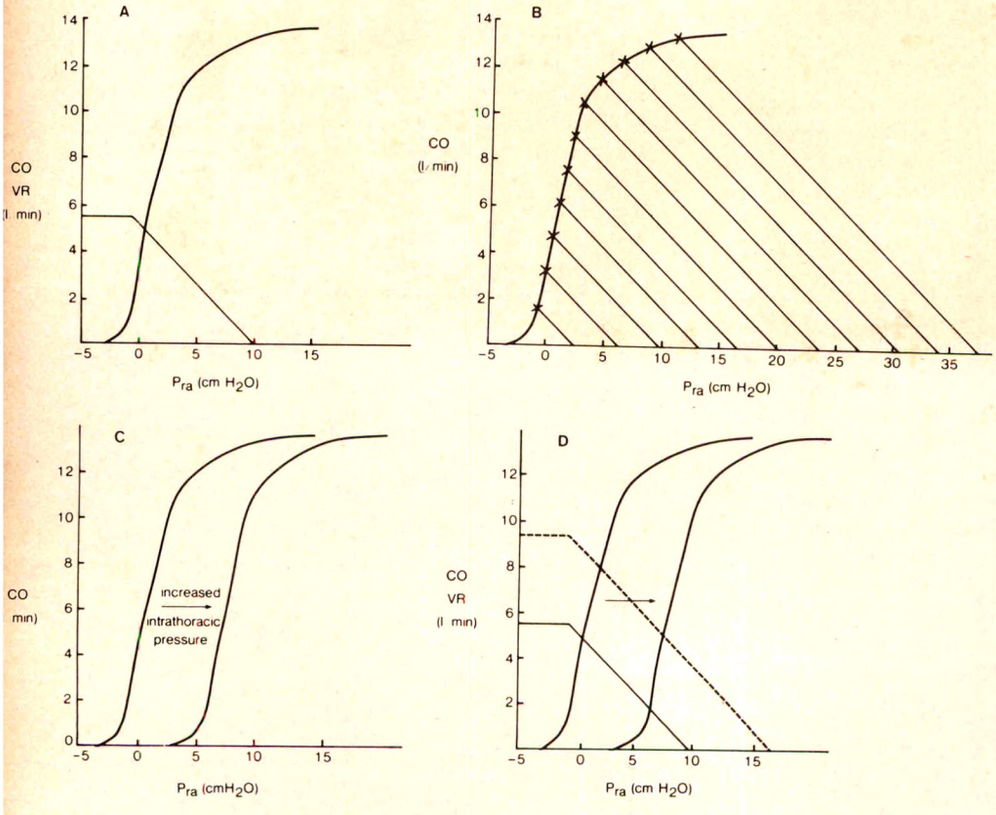

FIGURE 8. A, a venous return (VR) curve and a cardiac function curve are plotted together. The intersection of the two curves determines cardiac output (CO). **B,** the technique for determining a cardiac function curve. Heart filling is increased by a progressive increase in mean systemic pressure; the resulting cardiac output and right atrial pressure (P_{ra}) are plotted. **C,** with no change in cardiac function, an increase in intrathoracic pressure shifts the cardiac function curve to the right. This occurs because at the same right heart volume and the same transmural right atrial pressure, right atrial pressure is increased in relation to atmospheric pressure. **D,** for a parallel shift in the cardiac function curve, mean systemic pressure must be increased to maintain cardiac output.

diastolic compliance of the right ventricle is relatively high; a large change in volume is associated with only a modest change in pressure. If this increase in end-diastolic right ventricular pressure reflects the change in right atrial pressure, then the latter would change relatively little with major changes in right heart volume. In the face of an increased output load, right ventricular volume increases.[10,11] Because this volume change is associated with a small change in end-diastolic right ventricular pressure, and therefore right atrial pressure, only modest increases in mean systemic pressure are necessary to maintain normal cardiac output.

Response to Increased Right Heart Afterload

In respiratory failure, either acute or chronic, there may be an increase in afterload on the right heart. Experiments to obtain data on complete right heart function curves at various loads have not been done. Such experiments might show that changes in contractility may occur in the chronic state that are not present under acute loading conditions. However, it is clear that increased load in the right heart chambers leads to increased pressure in the right atrium if cardiac output is maintained. This implies that mean systemic pressure also must have increased. One of the mechanisms available for increasing mean systemic pressure is retention of fluid to increase vascular stressed volume. Although this can lead to clinical signs of right heart failure, in fact, the right heart chambers may be operating normally but at a higher pressure. Even though in the intact animal or in man, the right heart chambers are part of an interdependent system, useful information about right heart function in response to increased load can be obtained from pressure-volume studies of the right ventricle in isolated hearts.

Figure 9A, redrawn from Maughan et al.,[10] shows that the maximal systolic tension curve and the diastolic tension curve are both linear for a range of total tension of about 10 to 80 mm Hg. In Figure 9B, redrawn from Janicki and Weber,[11] who also studied the isolated dog heart, the curve includes a pressure-volume relation of the right ventricle with the pericardium intact as well as with the pericardium removed, which was the case in the study of Maughan et al.[10] The latter curves differ slightly from those of Maughan et al. in that they are more curvilinear at higher loads. Because heart rate was kept constant by pacing in both studies, changes in stroke volume can be translated directly into changes in cardiac output.

Because cardiac function curves are determined at a fixed load, if a plot is made of stroke volume versus end-diastolic right ventricular pressure at a given load, a curve equivalent to the cardiac function curve is generated. Stroke volume-right ventricular end-diastolic pressure points at a given right ventricular pressure load can be obtained from the data in Figure 9. This is done by drawing a line perpendicular to a given right ventricular pressure. Two such lines can be seen in Figure 9A, one at 20 and one at 40 mm Hg. At the point that this perpendicular line crosses the maximal systolic tension curve, a line parallel to the ordinate is drawn. The intersection of this new line and the diastolic tension curve defines the minimal volume necessary for the ventricle to develop the desired tension. At this point, the stroke volume would be zero and end-diastolic right ventricular pressure defined. Figure 9A shows that, as the load increases, the right ventricular end-diastolic pressure demonstrated in this way increases. However, for equal increments in stroke volume at each load, the change in right ventricular and diastolic pressures would

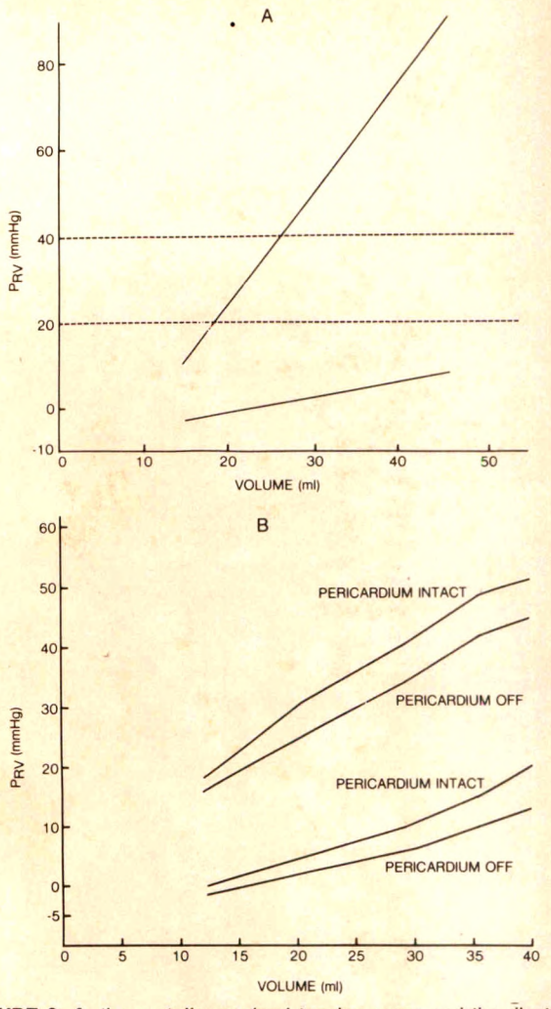

FIGURE 9. A, the systolic maximal tension curve and the diastolic tension curve, redrawn from Maughan et al.[10] The **dashed lines** identify the point at which a right ventricular pressure (P_{RV}) of 20 or 40 mm Hg crosses the maximal tension curve. It can be seen that the state of diastolic filling necessary for the right ventricle to reach the greater developed tension is increased. Therefore, right ventricular diastolic pressure is greater. However, if stroke volume were to increase at either load, the change in right ventricular end-diastolic pressure would be the same. The diastolic curve also shows that as right ventricular volume increases to about 45 ml, the end-diastolic pressure in the right ventricle increases to only about 5 mm Hg. **B,** right ventricular pressure-volume curves with the pericardium intact or removed. These curves are redrawn from Janicki and Weber.[11]

be identical. When the relation between stroke volume and right ventricular end-diastolic pressure obtained in this way is plotted (Fig. 10), changes in right ventricular afterload are shown to cause a parallel shift in the function curve to the right. This parallel shift is analogous to the effect of increased pleural pressure described earlier. Therefore, as afterload in the right ventricle increases within the limits of these studies, cardiac output can be maintained by increasing mean systemic pressure (Fig. 8D).

Figure 9 also shows that, as load increases, end-diastolic volume increases if stroke volume is constant. These changes would lead to a larger end-systolic volume and a reduced ejection fraction, but no change in the slope of the cardiac function curve. A potential limit

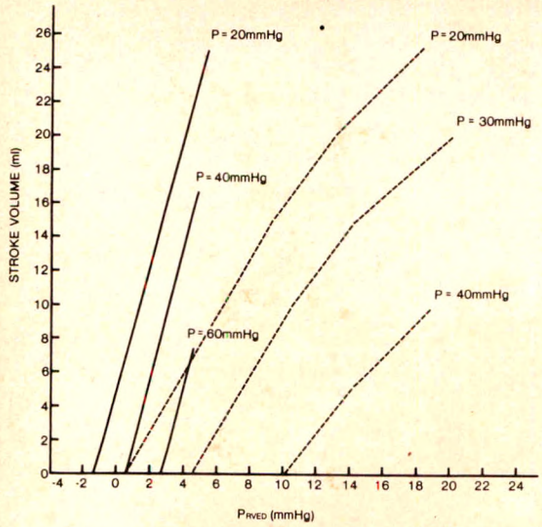

FIGURE 10. This figure, derived from data presented in Figure 9, shows the relation between right ventricular end-diastolic pressure (P_{RVED}) and stroke volume at various right ventricular loads identified by the pressure (P) noted at the top of each curve. The data from which these curves were derived were obtained at a constant heart rate. Therefore, changes in stroke volume can be taken as changes in cardiac output. If right ventricular end-diastolic pressure can be taken as similar to right atrial pressure, then the relation displayed is similar to cardiac function curves. With increasing load, the curves exhibit a parallel shift to the right and down.

to the maintenance of cardiac output would occur if these stroke volume–right ventricular end-diastolic pressure curves exhibited a plateau. However, an increase in heart rate could overcome this. Indeed, in a study by Stool et al.,[12] when stroke volume decreased in intact dogs given acute increases in right heart output load, heart rate increased and cardiac output was maintained.

This analysis helps explain why cardiac glycosides might not be of value in the management of some patients with cor pulmonale. The cardiac glycosides would be expected to increase the slope of the cardiac function curve, but because these curves are already relatively steep and may only be shifted to the right, improvement in right atrial pressure at a given cardiac output would be modest. This effect may be more than balanced by a decrease in mean systemic pressure in the absence of hypervolemia, because cardiac glycosides have been shown to increase unstressed vascular volume in dogs.[13] This could result in a decrease in the gradient between mean systemic and right atrial pressures and a reduction in venous return and, therefore, in cardiac output.

This analysis also points out a potential danger in the overvigorous use of diuretic agents in the management of patients with cor pulmonale. Excessive use of such agents could lead to a significant decrease in mean systemic pressure resulting from a decrease in intravascular volume. Ankle edema might be alleviated, but the cost might be a reduction in cardiac output.

Conclusions

We have analyzed the circulation in terms of a closed loop system in which cardiac output cannot exceed venous return. Venous return is determined by the difference between mean systemic and right atrial pressures at a constant resistance to venous return. Mean systemic pressure can be changed by altering the vascular stressed volume or systemic vascular compliance. Changes in right atrial pressure are more complex. For the purposes of venous return, since mean systemic pressure is determined in relation to atmospheric pressure, right atrial pressure must be expressed in relation to atmospheric pressure. Right atrial pressure is increased in relation to atmospheric pressure by factors such as positive pressure ventilation, positive end-expiratory pressure and increased volume in the right heart chambers secondary to increased afterload, such as might occur with acute or chronic respiratory failure. Through interdependent mechanisms, right atrial pressure also may be increased by pericardial effusion or left heart dysfunction. As right atrial pressure increases, mean systemic pressure must increase to maintain a normal cardiac output, and these changes may lead to signs of right heart failure. For these signs to occur, the right heart chambers need not have a depressed function curve, but merely be shifted to the right on the cardiac output-right atrial pressure axis.

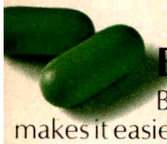
KAON CL-10™
(potassium chloride)
10 mEq Controlled Release Tablets

Easy-to-remember b.i.d. dosage

Just one KAON CL™-10 wax-matrix tablet b.i.d. supplies 20 mEq KCl. Two tablets b.i.d. supply 40 mEq KCl.



Easy to comply

B.i.d. instead of conventional t.i.d. dosage makes it easier for your patients to follow your instructions...increases likelihood of full compliance.

Easy to take, easy to carry

KAON CL-10 tablets have no taste or aftertaste...can be easily carried anywhere.

Easy dosage adjustment

Dosage may be individually adjusted, based on logical, easy-to-determine multiples of 10.

Easy on the purse

KAON CL-10 tablets offer your patients greater economy because fewer tablets deliver the same amount of potassium at a lower cost.

Easy on the GI tract

Special wax-matrix delivery system permits gradual release of KCl over several hours to minimize high localized concentrations in the GI tract, thus minimizing the chance of GI irritation. The frequency of small bowel lesions with wax-matrix tablets is less than one per 100,000 patient years.

for patients who can't or won't take liquid supplements

Brief Summary

Description: Kaon Cl™-10 mEq is a sugar coated (not enteric-coated) tablet containing 750 mg potassium chloride (equivalent to 10 mEq potassium chloride) in a wax matrix. This formulation is intended to provide a controlled release of potassium from the matrix to minimize the likelihood of producing high localized concentrations of potassium within the gastrointestinal tract.

Indications: BECAUSE OF REPORTS OF INTESTINAL AND GASTRIC ULCERATION AND BLEEDING WITH SLOW RELEASE POTASSIUM CHLORIDE PREPARATIONS, THESE DRUGS SHOULD BE RESERVED FOR THOSE PATIENTS WHO CANNOT TOLERATE OR REFUSE TO TAKE LIQUIDS OR EFFERVESCENT POTASSIUM PREPARATIONS OR FOR PATIENTS IN WHOM THERE IS A PROBLEM OF COMPLIANCE WITH THESE PREPARATIONS.

For therapeutic use in patients with hypokalemia with or without metabolic alkalosis, in digitalis intoxication and in patients with hypokalemic familial periodic paralysis.

For the prevention of potassium depletion when the dietary intake is inadequate in the following conditions: Patients receiving digitalis and diuretics for congestive heart failure; hepatic cirrhosis with ascites, states of aldosterone excess with normal renal function, potassium-losing nephropathy, and with certain diarrheal states.

The use of potassium salts in patients receiving diuretics for uncomplicated essential hypertension is often unnecessary when such patients have a normal dietary pattern. Serum potassium should be checked periodically, however, and if hypokalemia occurs, dietary supplementation with potassium-containing foods may be adequate to control milder cases. In more severe cases supplementation with potassium salts may be indicated.

Contraindications: Potassium supplements are contraindicated in patients with hyperkalemia since a further increase in serum potassium concentration in such patients can produce cardiac arrest. Hyperkalemia may complicate any of the following conditions: Chronic renal failure, systemic acidosis such as diabetic acidosis, acute dehydration, extensive tissue breakdown as in severe burns, adrenal insufficiency, or the administration of a potassium-sparing diuretic (e.g., spironolactone, triamterene).

Wax-matrix potassium chloride preparations have produced esophageal ulceration in certain cardiac patients with esophageal compression due to enlarged left atrium. Potassium supplementation, when indicated in such patients, should be with a liquid preparation.

All solid dosage forms of potassium chloride supplements are contraindicated in any patient in whom there is cause for arrest or delay in tablet passage through the gastrointestinal tract. In these instances, potassium supplementation should be with a liquid preparation.

Warnings: Hyperkalemia—In patients with impaired mechanisms for excreting potassium, the administration of potassium salts can produce hyperkalemia and cardiac arrest. This occurs most commonly in patients given potassium by the intravenous route but may also occur in patients given potassium orally. Potentially fatal hyperkalemia can develop rapidly and be asymptomatic. The use of potassium salts in patients with chronic renal disease, or any other condition which impairs potassium excretion, requires particularly careful monitoring of the serum potassium concentration and appropriate dosage adjustment.

Interaction with Potassium Sparing Diuretics—Hypokalemia should not be treated by the concomitant administration of potassium salts and a potassium-sparing diuretic (e.g., spironolactone or triamterene) since the simultaneous administration of these agents can produce severe hyperkalemia.

Gastrointestinal Lesions—Potassium chloride tablets have produced stenotic and/or ulcerative lesions of the small bowel and deaths. These lesions are caused by a high localized concentration of potassium ion in the region of a rapidly dissolving tablet, which injures the bowel wall and thereby produces obstruction, hemorrhage, or perforation. Kaon Cl™-10 mEq (potassium chloride) is a wax-matrix tablet formulated to provide a controlled rate of release of potassium chloride and thus to minimize the possibility of a high local concentration of potassium ion near the bowel wall. While the reported frequency of small bowel lesions is much less with wax-matrix tablets (less than one per 100,000 patient years) than with enteric-coated potassium chloride tablets (40-50 per 100,000 patient years) cases associated with wax-matrix tablets have been reported both in foreign countries and in the United States. In addition, perhaps because the wax-matrix preparations are not enteric-coated and release potassium in the stomach, there have been reports of upper gastrointestinal bleeding associated with these products. The total number of gastrointestinal lesions remains less than one per 100,000 patient years. Kaon Cl-10 mEq should be discontinued immediately and the possibility of bowel obstruction or perforation considered if severe vomiting, abdominal pain, distention, or gastrointestinal bleeding occurs.

Metabolic Acidosis—Hypokalemia in patients with metabolic acidosis should be treated with an alkalinizing potassium salt such as potassium bicarbonate, potassium citrate, potassium acetate, or potassium gluconate.

Precautions: The diagnosis of potassium depletion is ordinarily made by demonstrating hypokalemia in a patient with a clinical history suggesting some cause for potassium depletion. In interpreting the serum potassium level, the physician should bear in mind that acute alkalosis per se can produce hypokalemia in the absence of a deficit in total body potassium while acute acidosis per se can increase the serum potassium concentration into the normal range even in the presence of a reduced total body potassium. The treatment of potassium depletion, particularly in the presence of cardiac disease, renal disease, or acidosis requires careful attention to acid-base balance and appropriate monitoring of serum electrolytes, the electrocardiogram, and the clinical status of the patient.

Adverse Reactions: The most common adverse reactions to oral potassium salts are nausea, vomiting, abdominal discomfort and diarrhea. These symptoms are due to irritation of the gastrointestinal tract and are best managed by diluting the preparation further, taking the dose with meals, or reducing the dose.

The most severe adverse effects are hyperkalemia (see Contraindications, Warnings and Overdosage) and gastrointestinal obstruction, bleeding or perforation (see Warnings).

Overdosage: The administration of oral potassium salts to persons with normal excretory mechanisms for potassium rarely causes serious hyperkalemia. However, if excretory mechanisms are impaired or if potassium is administered too rapidly intravenously, potentially fatal hyperkalemia can result (see Contraindications and Warnings). It is important to recognize that hyperkalemia is usually asymptomatic and may be manifested only by an increased serum potassium concentration and characteristic electrocardiographic changes (peaking of T-waves, loss of P-wave, depression of S-T segment, and prolongation of the QT interval). Late manifestations include muscle-paralysis and cardiovascular collapse from cardiac arrest.

Treatment measures for hyperkalemia include the following:

1. Elimination of foods and medications containing potassium and of potassium-sparing diuretics.
2. Intravenous administration of 300 to 500 ml/hr of 10% dextrose solution containing 10-20 units of crystalline insulin per 1,000 ml.
3. Correction of acidosis, if present, with intravenous sodium bicarbonate.
4. Use of exchange resins, hemodialysis, or peritoneal dialysis.

In treating hyperkalemia, it should be recalled that in patients who have been stabilized on digitalis, too rapid a lowering of the serum potassium concentration can produce digitalis toxicity.

Caution: Federal law prohibits dispensing without prescription.

How Supplied: Bottles of 100 and 500; Stat-Pak® (Unit-Dose) box of 100.

- to reduce fever
- to aid in vascular headache
- to suppress platelet aggregation

The only antiprostaglandin therapy that has passed the test of time and experience, aspirin is probably the most widely used drug in the world. With the inclusion of Maalox® in the tablet, aspirin becomes Ascriptin®—keeping all its therapeutic effectiveness and reducing risk of GI intolerance—for even greater acceptability to occasional users as well as to patients on long-term or frequent dosage.

For the best of aspirin...

Ascriptin®

Aspirin, 325 mg ■ buffered with Maalox®, 150 mg

RECOMMENDED ASCRIPTIN® DOSE IN TIA's: 1300 mg/day
(two tablets b.i.d. or one tablet q.i.d.)

There is evidence that aspirin is safe and effective for reducing the risk of recurrent transient ischemic attacks or stroke in men who have had transient ischemia of the brain due to fibrin platelet emboli.
There is no evidence that aspirin is effective in reducing TIA's in women or is of benefit in the treatment of completed strokes in men or women. Patients presenting signs and symptoms to TIA's should have a complete medical and neurologic evaluation.
Consideration should be given to other disorders which resemble TIA's.
It is important to evaluate and treat, if appropriate, other disease associated with TIA's and strokes such as hypertension and diabetes.

Unusual mechanisms of spontaneous termination of atrioventricular (A-V) nodal reentrant tachycardia were observed in two patients during programmed electrical stimulation of the heart. In both patients the mechanism of termination was based on the use of another reentrant pathway than the one used during tachycardia. This pathway was located extranodally in one patient and intranodally in the other. The observations illustrate some of the complexities of reentry in the human heart and how they can play a role in spontaneous termination of A-V nodal tachycardia.

Observations in the animal heart[1,2] and data from programmed electrical stimulation in the human heart[3,4] support reentry as the most common mechanism for atrioventricular (A-V) nodal tachycardia. Reentry requires the presence of two interconnected pathways having different electrophysiologic properties. Termination of reentry occurs when refractory tissue halts the circulating impulse somewhere in the reentrant pathways. In this study we report observations on spontaneous termination of tachycardia in two patients with A-V nodal tachycardia, emphasizing how a third pathway that is connected to the reentry circuit can result in refractoriness in the reentry circuit and termination of the arrhythmia.

Methods

Patient 1 was a 20 year old man with A-V nodal tachycardia at a rate of 200/min. Patient 2 was a 70 year old man with A-V nodal tachycardia at a rate of 150/min. After the patients gave informed consent, they underwent an electrophysiologic study in the resting postabsortive, nonsedated state. Neither patient was receiving medication at the time of study. With use of the femoral approach, catheters were placed for both stimulation and recording of intracardiac electrograms in the apex of the right ventricle, the bundle of His region, the high right atrium and the coronary sinus. Our stimulation protocol has previously been described.[5] Both patients underwent a complete study. Only relevant data will be presented.

Criteria for the diagnosis of A-V nodal reentrant tachycardia: The diagnosis of A-V nodal tachycardia was based largely on exclusion of the use of an accessory A-V pathway as the retrograde limb of the tachycardia circuit and exclusion of an atrial site of origin of the tachycardia. The exclusion criteria were as follows: (1) Supraventricular tachycardia inducible by atrial premature beats related to A-V nodal delay.[3–4,6] (2) Simultaneous activation of atria and ventricles during tachycardia.[6] (3) H-A interval during tachycardia independent of H-V interval or bundle branch block pattern. (4) Persistence of tachycardia during A-V block distal to the bundle of His area (Patient 1). (5) Inability to advance atrial activation during tachycardia by ventricular premature beats given at the time of refractoriness of the bundle of His.[7] (This observation does not exclude the presence of an accessory A-V pathway, but the opposite finding would prove its presence.[6]) (6) Ventriculoatrial conduction during ventricular pacing and after ventricular premature beats related to depolarization of the bundle of His[8] and subnodal delay of ventricular premature beats.[9] (7) Similar atrial activation

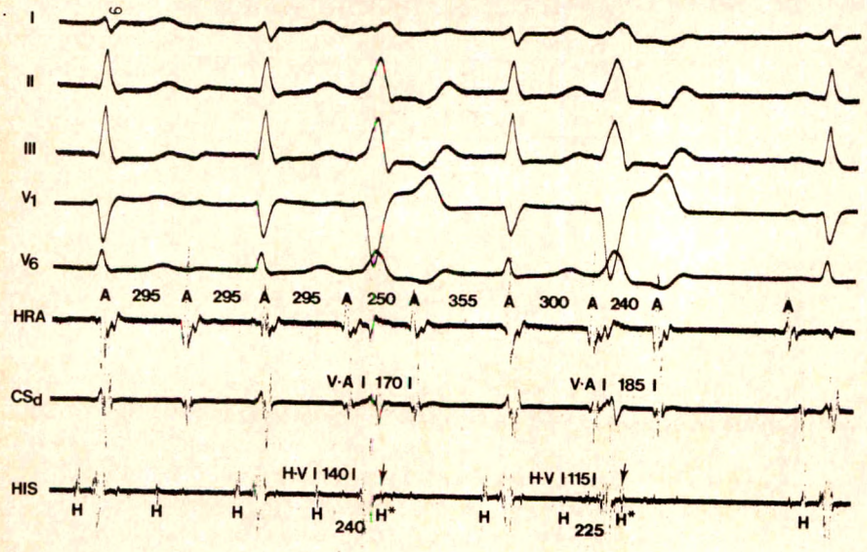

FIGURE 1. Case 1. Atrioventricular (A-V) nod tachycardia originally showing 2:1 block distal the bundle of His. After recovery of 1:1 A-V co duction over the right bundle branch (third QR complex, with a left bundle branch block confi uration) subsequent atrial activation is advance When this pattern is repeated (fifth QRS comple tachycardia is terminated. Indicated are th tachycardia cycle length in ms, the H-V interv preceding the widened QRS complexes and th V-A interval following these widened QRS com plexes as measured in the distal coronary sinu (CSd) lead for clarity. **Arrows** point to possibl retrograde His bundle potentials labeled H*. Se text and Figure 2 for explanation. Leads I, II, III, V and V_6 were simultaneously recorded with a hig right atrial (HRA), a distal coronary sinus and a Hi bundle electrogram.

pattern during tachycardia and after retrograde conduction during ventricular pacing, suggesting that in both circumstances the same pathway was used for retrograde conduction.

Conventional definitions were used for refractory periods. The A-V nodal conduction curve was considered discontinuous if increasing the prematurity of the test pulse (atrial or ventricular) by 10 ms resulted in a sudden increase in A-V nodal conduction time by 50 ms or more. This sudden unexpected increase in A-V nodal conduction time of a premature beat suggests a shift in conduction from a fast to a slow A-V nodal pathway.[1–4,6,7]

Results

Patient 1: Termination of A-V nodal tachycardia by bundle branch reentry: A-V nodal tachycardia with a cycle length of 295 ms originally showed 2:1 block distal to the bundle of His (Fig. 1). During recovery of 1:1 A-V conduction the first QRS complex shows a prolonged H-V interval (140 ms) and a complete left bundle branch block configuration. This QRS complex is followed by atrial activation with the sequence of atrial activation similar to the one recorded during tachycardia and occurring 45 ms earlier than expected, indicating that the atrial complex is not the result of regular impulse formation during tachycardia. The fifth QRS complex during tachycardia again shows a left bundle branch block pattern, but with an H-V interval of 115 ms. This QRS complex is followed by atrial activation occurring earlier than expected. After this atrial complex the tachycardia terminates.

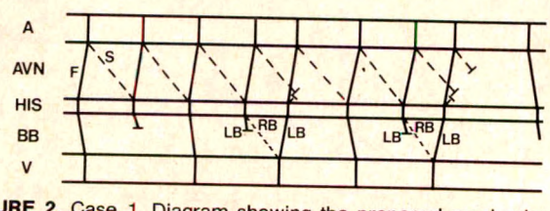

FIGURE 2. Case 1. Diagram showing the proposed mechanism of termination of tachycardia in Figure 1. A = atrium; AVN = atrioventricular node; BB = bundle branches; F = fast A-V nodal pathway; LB = left bundle branch; RB = right bundle branch; S = slow A-V nodal pathway; V = ventricle. See text.

The H-A interval stays the same in spite of changing H-V intervals during the aberrant complexes, or in spite of block of conduction to the ventricles at a site distal to the bundle of His. We postulate (Fig. 2) that during left bundle branch block the impulse traveling to the ventricles over the right bundle branch is able to invade in retrograde fashion the left bundle branch and reenters the A-V node. Retrograde conduction over the fast A-V nodal pathway allows premature activation of the atrium.

In Figures 1 and 3 possible retrograde His bundle potentials following the aberrant QRS complexes are identified. It was considered that they should precede the atrial echo by 80 ms or more (the H-A interval during tachycardia). An inverse relation is observed between the H-V interval and the V-H interval after the aberrant QRS complexes, (the V-H interval measures 100 ms after an H-V interval of 140 ms, and 110 ms after an H-V interval of 115 ms). The V-A interval following the aberrant complexes (as measured from the ventriculogram in the distal coronary sinus lead to the onset of atrial activation in the same lead) changes in the absence of changes in the bundle branch block pattern. This observation suggests that a free wall bypass tract is not the pathway used for retrograde conduction. Tachycardia is terminated depending on the retrograde and anterograde input in the A-V nodal pathways as reflected by the H-H and A-A intervals. After the first aberrant QRS complex the H-H interval measures 240 ms (Fig. 1) and the A-A interval 250 ms. This results in some degree of concealed penetration of the impulse in the slow A-V nodal pathway (Fig. 2) and collision with the anterograde front within this pathway, whereas retrograde conduction to the atria takes place over the fast A-V nodal pathway. The atrial complex is conducted in anterograde manner with a transient increase in the slow pathway conduction time. However, after the second aberrant QRS complex both the H-H interval (225 ms) and the A-A interval (240 ms) are shorter (Fig. 1). This shortening results in a major degree of concealed penetration of the impulse in the slow pathway that, in combination with a shorter A-A interval, results in block of impulse conduction in the slow pathway and termination of tachycardia (Fig. 1 and 2).

Occasionally right bundle branch block was observed during the change from 2:1 to 1:1 A-V conduction. This also resulted in the echo phenomenon (Fig. 3). However, because of the retrograde and anterograde input in the A-V nodal pathways

(H-H interval 240 ms and A-A interval 260 ms after the aberrant QRS complex) a fully compensatory pause followed and tachycardia continued. In this patient atrial premature beats delivered during atrial pacing at a basic cycle length of 600 ms did not result in aberrant conduction to the ventricles, the shortest attainable H_1-H_2 interval measuring 330 ms.

Patient 2. Termination of A-V nodal tachycardia by a sudden change in another anterograde A-V nodal pathway: An A-V nodal tachycardia with anterograde conduction over a "slow" pathway and retrograde conduction over a "fast" pathway (Fig. 4) was terminated spontaneously by a cycle that (1) was 115 ms shorter than the cycles seen during tachycardia, and (2) was not followed by retrograde conduction to the atria. This mode of spontaneous termination was repeatedly observed and probably can be explained by the A-V nodal conduction curves shown in Figure 5. During single test stimulation of the right atrium at a basic cycle length of 500 ms, several discontinuities in the A_2-H_2 curve are seen. This was also during stimulation with a basic cycle length of 460 ms. These findings support the presence of either more than one "slow" pathway or delay in a final common pathway. The former hypothesis is supported by the fixed H to atrial echo interval at the time of initiation of tachycardia irrespective of the preceding A-H interval. If a final common pathway were responsible for delay in conduction to the His bundle and the "jumps" in the conduction curve, a changing relation between His bundle activation and atrial echo would have been observed.

We postulate that in this patient tachycardia terminates spontaneously because of conduction over a "slow" pathway that is not slow enough to overcome retrograde refractoriness of the "fast" retrograde pathway (Fig. 6). Although the anterograde and retrograde refractory periods of the fast pathway need not be equal, the anterograde refractory period of the fast pathway measured 290 ms and the H-H interval terminating tachycardia measured 280 ms (a lesser value). After initiation of tachycardia (Fig. 6), we postulate a decreasing concealment in the third pathway that is finally relieved, allowing anterograde conduction over this pathway, the impulse colliding in the slow pathway with the anterograde front and blocking in the fast pathway because it is entering at a time when the pathway is still refractory.

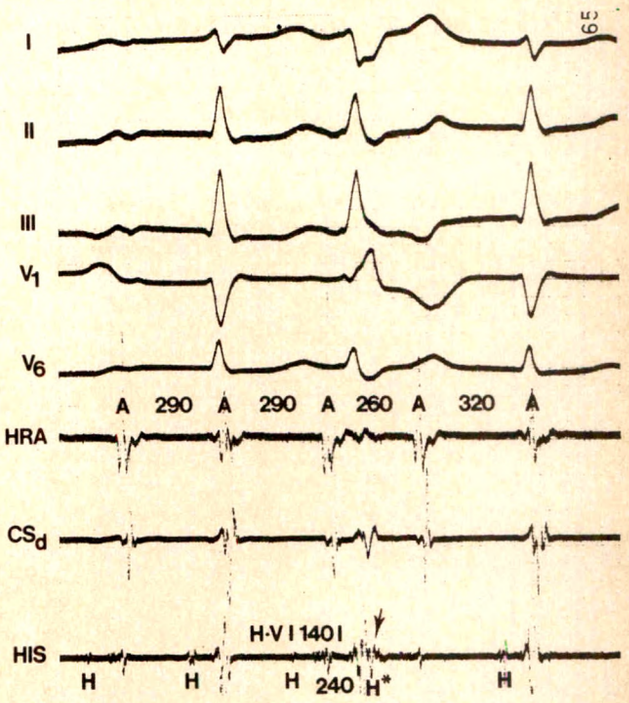

FIGURE 3. Case 1. A-V nodal tachycardia with 2:1 block distal to the bundle of His showing recovery of conduction over the left bundle branch (second QRS complex, with a right bundle branch block configuration). Subsequent atrial activation is advanced but tachycardia continues. Same leads and labeling as in Figure 1. See text.

Discussion

A third pathway with bundle branch reentry: In these two patients the findings strongly suggest that reentry into the tachycardia circuit over a third pathway was responsible for termination of the arrhythmia. This third pathway was not involved in the reentrant pathways during initiation and perpetuation of tachycardia. Atrial echo beats based on reentry over the bundle branches have been demonstrated to occur.[10–12] As in those studies, the atrial echoes in our Patient 1 required the presence of block in one of the bundle branches and sufficient delay in conduction over the other bundle branch to complete a reentrant cycle. The time of arrival of the impulse in the A-V nodal pathways (in both anterograde and retrograde directions as reflected by the H-H and A-A intervals following the aberrant complex) was crucial for termination of the reentrant movement. It seems unlikely that the widened QRS complexes represented ventricular extrasystoles occurring late in diastole. Ventricular premature beats were not observed to occur spontaneously throughout the investigation and, as shown, advancement of subsequent atrial activation was observed during both left and right bundle branch block-shaped QRS complexes. The range of H-V intervals preceding these widened QRS complexes is in keeping with previous clinical observations[10] and the results of experimental studies.[12]

An inverse relation between H-V and V-H intervals during the widened QRS complexes was demonstrated in our Patient 1, supporting the concept of bundle branch reentry.[10] In this patient we could exclude the presence of an extranodal accessory pathway. Depolarization of the bundle of His occurred twice during H-H intervals of 240 to 225 ms (Fig. 1 and 3). Experimental studies[12] have shown that retrograde depolarization of the His bundle can occur as soon as 160 ms after its anterograde depolarization. The observation of bundle branch block with slow conduction over the contralateral branch with advancement of subsequent atrial activation makes bundle branch reentry the most plausible explanation for termination of tachycardia in this patient. Unfortunately, bundle branch block and atrial echoes were not observed during atrial premature beats delivered during pacing of the right atrium at a basic cycle length of 600 ms. Their absence might have occurred because the H-H interval of 300 ms during tachycardia could result in concealment in the bundle branch system, allowing development of bundle branch block patterns, whereas such concealed conduction presumably did not occur during atrial pacing at a basic cycle length of 600 ms.

Anterograde intranodal conduction over a third A-V nodal pathway: In Patient 2 a sudden shortening in the cycle length of reentry was followed by termina-

tion of tachycardia. The degree of shortening is too great to be accounted for by a sudden change in autonomic tone. The most attractive hypothesis to explain this phenomenon is anterograde intranodal conduction over a different A-V nodal pathway with slow conduction time. The finding of several discontinuities in the A-V nodal conduction curve might support this theory. It is of interest that the A-H interval after the first break in the A-V nodal conduction curve is similar to the A-H interval before termination of tachycardia, measuring 230 and 215 ms, respectively (Fig. 4 and 5). We cannot exclude the possibility that a His bundle extrasystole was responsible for termination of tachycardia and the apparent shortening of the A-H interval. Also we do not know the validity of comparing the A-H interval terminating tachycardia with the A-H interval after the

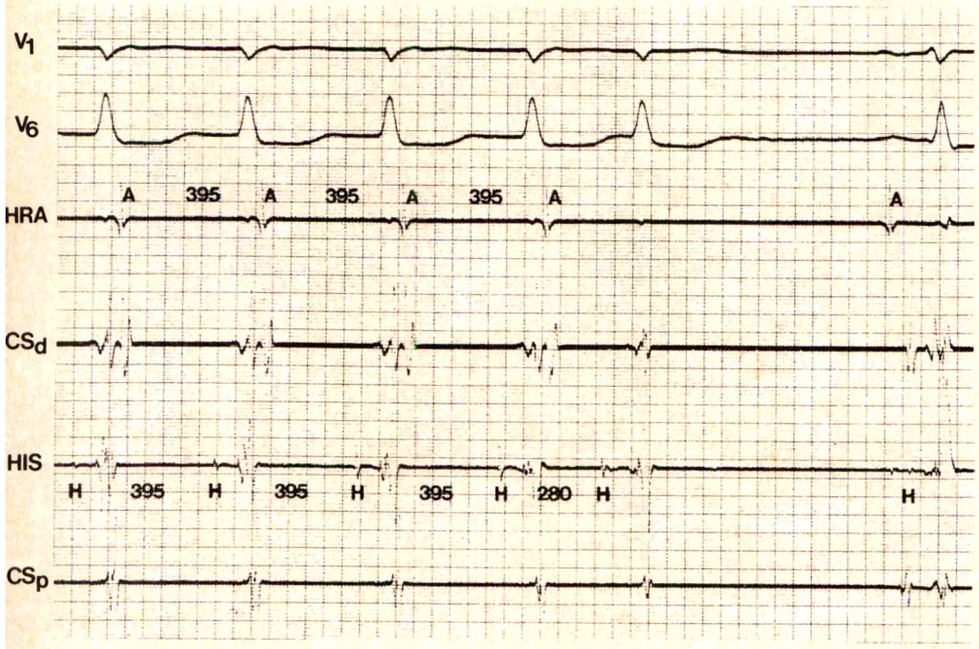

FIGURE 4. Case 2. A-V nodal tachycardia with a cycle length of 395 ms. Tachycardia terminates after sudden shortening in the H-H interval by 115 ms, corresponding to 115 ms shortening in the A-H interval. This repeatedly observed phenomenon was not preceded by any changes in time relations during the tachycardia. Leads V_1 and V_6 were simultaneously recorded with four endocavitary electrograms. CSp = Proximal coronary sinus electrogram.

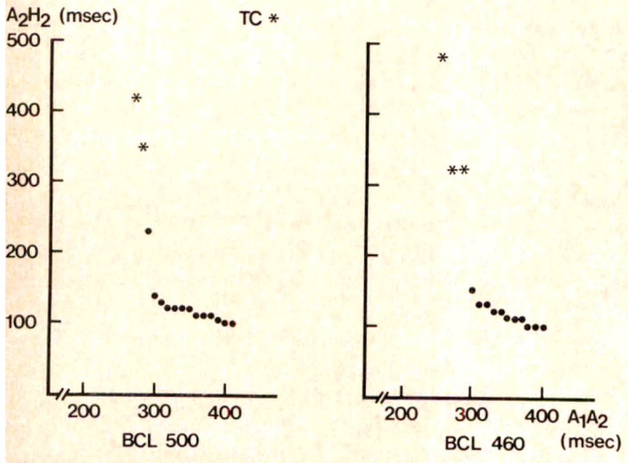

FIGURE 5. Case 2. Relation between the A_1–A_2 intervals (**abscissa**) during pacing of the high right atrium at basic cycle lengths of 500 and 460 ms. Three discontinuities in the A-V nodal conduction curve were observed during atrial pacing with a basic cycle length of 500 ms (**left**), and two when the basic cycle length of pacing was decreased to 460 ms (**right**). TC = atrial premature beats initiating tachycardia.

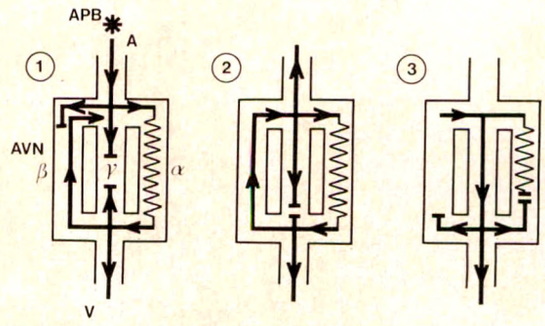

FIGURE 6. Case 2. Diagram illustrating the proposed mechanism of termination of tachycardia as observed in Figure 4. α, β and γ represent three A-V nodal pathways. In panel 1, an atrial premature beat (APB) is blocked in pathways β and γ and initiates tachycardia after anterograde conduction over pathway α (the slowest conducting pathway) and retrograde conduction over pathway β (the fastest pathway). Pathway γ is maintained refractory because of concealed anterograde and retrograde penetration of impulses during tachycardia. In panel 2, decreasing concealed penetration in pathway γ in the retrograde direction is postulated. In panel 3, after recovery of conduction in the anterograde direction in pathway γ the impulse is conducted to the ventricles with a shorter than expected A-H interval. The impulse blocks in pathway β because of refractoriness of this pathway, and collides in pathway α with the anterograde impulse, resulting in termination of tachycardia. Abbreviations as in Figure 2.

first break in the A-V nodal conduction curve of the left graph from Figure 5 when cycle lengths are different. However, we believe that the reproducibility of our observations, the several discontinuities in the A-V nodal conduction curve and the mode of termination of tachycardia suggest the availability of several A-V nodal pathways. The availability of several A-V nodal pathways has already been advanced from animal studies.[2] In Patient 2 a similar A-V nodal conduction time was observed not to initiate or to terminate tachycardia, thus suggesting the use of a third A-V nodal pathway that was not slow enough to overcome refractoriness of the retrograde A-V nodal pathway used during tachycardia.

Implications: In these two patients, sudden unexpected conduction over another reentrant pathway accounted for termination of the arrhythmia. Why these pathways were suddenly able to conduct is difficult to explain. Although, the factors leading to the new reentrant pathway terminating tachycardia could be recognized in Patient 1, they remain unclear in Patient 2. One can speculate that differences in degree of concealed penetration of the impulse in potential reentrant circuits or changes in refractoriness and conduction velocity during tachycardia might have played a role. However, our present methods of investigation in the intact human heart are not refined enough to uncover most of these complex mechanisms.

Left atrial enlargement can usually be detected accurately using M mode echocardiography. However, in the presence of heart disease, asymmetric enlargement may lead to inaccurate assessment of left atrial size and shape. Pericardial effusion can usually be diagnosed on the basis of characteristic M mode echocardiographic findings. However, false positive patterns sometimes occur with the use of this single dimensional technique. Three patients with a greatly enlarged left atrium are described whose M mode echocardiogram suggested significant posterior pericardial fluid accumulation. In each patient, two dimensional echocardiography detected portions of a huge left atrium that prolapsed behind the left ventricular posterior wall and mimicked an isolated posterior pericardial effusion. In one case a right anterior oblique left ventricular cineangiogram suggested the presence of a ventricular septal defect or a false aneurysm of the left ventricle due to the prolapsed left atrium. Because two dimensional echocardiography can provide accurate spatial orientation with visualization of intracardiac structures in relation to one another in real time, it can identify the presence of left atrial prolapse and play an important role in the differential diagnosis of isolated echo-free spaces behind the left ventricle detected with M mode echocardiography.

Echocardiography has been shown to be an accurate noninvasive technique for determining left atrial size[1–4] and detecting the presence of pericardial fluid.[5–8] However, with single dimensional M mode echocardiography, asymmetric left atrial enlargement can lead to inaccurate estimates of left atrial size.[9,10] Furthermore, false positive diagnoses of excessive posterior pericardial fluid accumulations have been noted with the use of M mode echocardiography in a variety of situations.[7] Two dimensional echocardiography is helpful in establishing the true nature of these false positive diagnoses in many instances.[8,11]

The purposes of this study are (1) to report the two dimensional echocardiographic features of left atrial prolapse behind the posterior wall of the left ventricle, which may occur in the presence of a huge left atrium and may mimic the presence of a posterior pericardial effusion, and (2) to report the left ventricular cineangiographic features that in one case suggested the presence of a ventricular septal defect or false aneurysm of the left ventricle.

Methods

Echocardiography: Routine M mode echocardiography was performed in three adult patients with suspected mitral valve disease. The transducer was placed along the left sternal border in the third to fourth intercostal space and angled to record portions of the mitral valve. The transducer was then angled inferiorly and laterally to record echoes from the left ventricular cavity and superiorly and medially to record echoes from the aortic root and left atrium. M

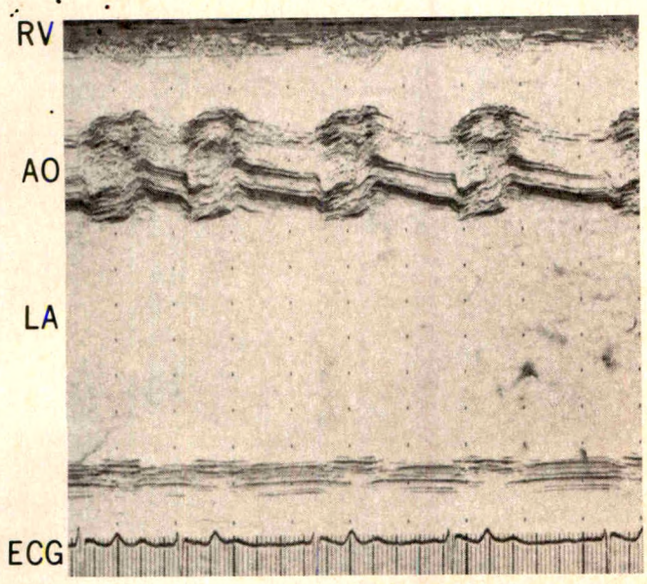

FIGURE 1. Case 1. M mode echogram of the aortic root (AO) demonstrating an anatomically abnormal aortic valve and a huge left atrium (LA) (75 mm). ECG = electrocardiogram; RV = right ventricle.

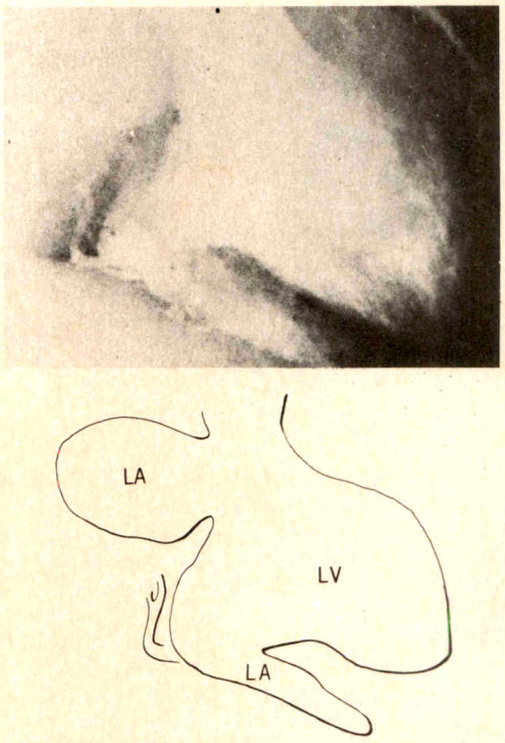

FIGURE 3. Case 1. A representative frame of the right anterior oblique left ventricular cineangiogram taken near end-diastole (**top**) and an artist's reconstruction of the frame (**bottom**). LA = left atrium; LV = left ventricle.

mode tracings were performed with a commercially available Picker 80-C ultrasonoscope with a 2.25 megahertz piezoelectric transducer focused at 7.5 cm. Examinations were recorded on light-sensitive paper using a strip chart recorder.

Sector scan echocardiograms were obtained using a Picker 80-C cardiac imager with a 2.25 megahertz transducer mechanically swept through a 60° arc at 300 sweeps/s. A long axis view of the heart was obtained by positioning the transducer in the third to fourth intercostal space to the left of the sternum and directing the plane of the sweep through the aortic root, the left atrium, the mitral valve and the left ventricle. A transverse view was obtained by rotating the transducer clockwise approximately 90°. Patients were initially placed in a supine position and later in the left lateral decubitus position for both M mode and two dimensional examinations.

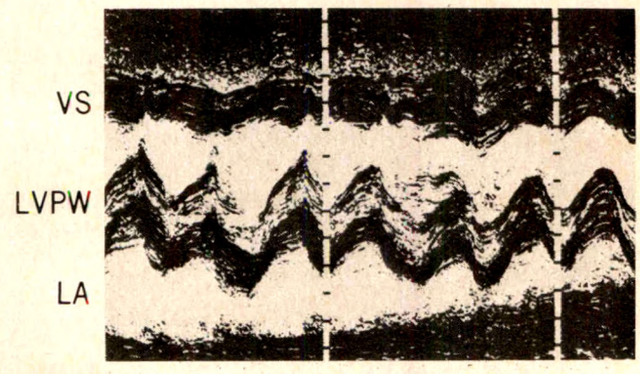

FIGURE 2. Case 1. M mode echocardiogram demonstrating an echo-free posterior space behind the left ventricle due to a prolapsed portion of a huge left atrium (LA). This finding is indistinguishable from that of posterior pericardial effusion. LVPW = left ventricular posterior wall; VS = ventricular septum.

These methods have been described by Nanda and Gramiak.[12]

Cineangiography: Left ventricular cineangiography was performed in the 30° right anterior oblique projection (Cases 1 and 3) and anterior and lateral biplane projections (Case 2) with injection of Renografin® 76. Filming was performed at 60 frames/s.

Case Reports

Case 1: A 65 year old woman with symptoms of congestive heart failure was referred for cardiac evaluation. The findings on physical examination, chest roentgenography and electrocardiography were compatible with mitral insufficiency. An M mode echocardiogram revealed rheumatic mitral valve disease, an anatomically abnormal aortic valve and a markedly enlarged left atrium measuring 75 mm (Fig. 1). An isolated echo-free space was noted behind the left ventricular posterior wall (Fig. 2), suggesting the presence of pericardial effusion. Cardiac catheterization revealed 2+ mitral regurgitation with an enlarged left atrium and no significant mitral valve diastolic gradient. Contrast material was also noted in an unusual location behind the left ventricle outside the confines of the left ventricular cavity (Fig. 3). This angiogram suggested the presence of either a ventricular septal defect or a false aneurysm of the left ventricle. Subsequent review of the right heart oxygen saturation levels revealed no oxygen step-up in the right heart chambers.

Two dimensional echocardiography was then performed. The longitudinal scan best demonstrated a huge left atrium that prolapsed behind the left ventricular posterior wall, ac-

FIGURE 4. Case 1. Two dimensional echocardiogram (**left**) and an artist's reconstruction (**right**). The echocardiogram is a longitudinal scan of the left ventricle demonstrating a huge left atrium (LA) prolapsing behind the left ventricle (LV). PV = prosthetic mitral valve; VS = ventricular septum.

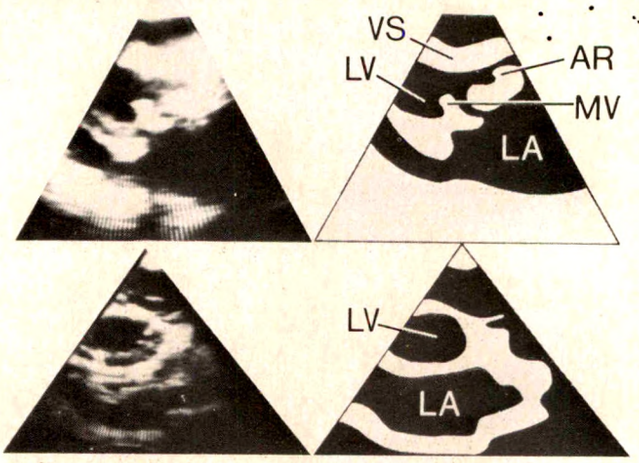

FIGURE 5. Case 2. Two dimensional echocardiograms (**left**) and an artist's reconstructions (**right**). **Upper panel,** longitudinal scan of the left ventricle demonstrating a huge left atrium (LA) prolapsing behind the left ventricle (LV). **Lower panel,** transverse cross-sectional scan of the left ventricle visualizing the posteriorly located left atrial prolapse. AR = aortic root; MV = mitral valve (rheumatic); VS = ventricular septum.

counting for both the posterior echo-free space behind the left ventricle in the M mode examination and the left ventricular cineangiographic findings. The patient subsequently underwent mitral valve replacement with a porcine heterograft. At operation a huge left atrium was found that prolapsed behind the left ventricular posterior wall. In addition, no pericardial effusion and no ventricular septal defect or false aneurysm of the left ventricle was present. After a stormy postoperative course, the patient recovered sufficiently to allow a second two dimensional echocardiographic examination. The results were similar to the preoperative findings except for the presence of a prosthetic mitral valve (Fig. 4).

Case 2: A 68 year old woman with a history of congestive heart failure was admitted to this center for evaluation, which revealed the presence of mitral stenosis and insufficiency. An M mode echocardiogram disclosed rheumatic mitral valve disease and left atrial enlargement. There was an echo-free space behind the left ventricular posterior wall, suggesting the presence of a posterior pericardial effusion. A two dimensional echocardiogram revealed a huge left atrial cavity that prolapsed behind the left ventricle (Fig. 5). Cardiac catheterization indicated critical mitral stenosis with mild mitral regurgitation. The lateral projection of a biplane left ventricular cineangiogram revealed a huge left atrium that prolapsed behind the left ventricle (Fig. 6). Mitral valve replacement was performed, and at operation a huge left atrium with an intracavitary clot was noted. No excessive pericardial fluid was present.

Case 3: A 62 year old woman was referred for cardiac evaluation, which revealed the presence of mitral stenosis and insufficiency. An M mode echocardiogram revealed rheumatic mitral valve disease, left atrial enlargement and the presence of an isolated echo-free space behind the left ventricular posterior wall, suggesting pericardial effusion. A right anterior oblique cineangiogram demonstrated a huge left atrium that prolapsed behind the left ventricle. Mitral valve replacement was performed, and at operation a huge left atrium was noted. However, approximately 500 cc of pericardial fluid was also found and removed.

In the immediate postoperative period a two dimensional transverse cross-sectional echocardiogram of the left ventricle again demonstrated a large echo-free space behind the left

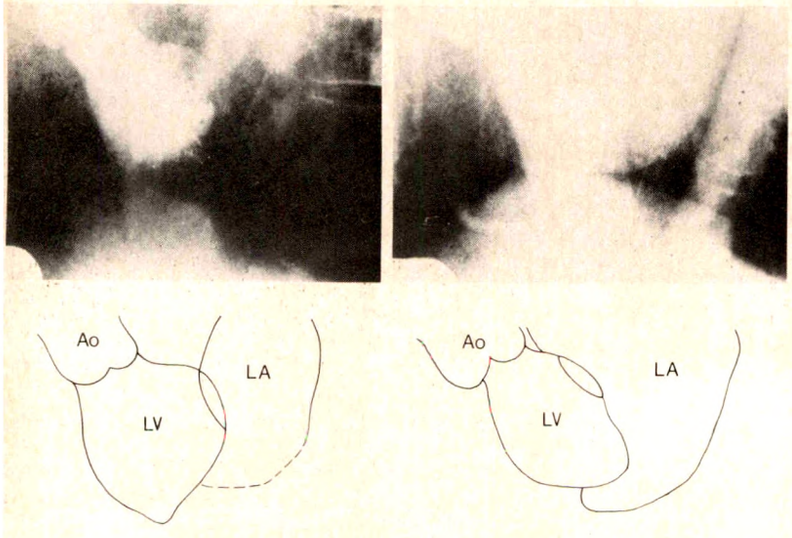

FIGURE 6. Case 2. **Top,** two representative frames from the lateral projection of the left ventricular cineangiogram, with an early contrast injection phase on the **left** and a late injection phase on the **right. Bottom,** an artist's reconstruction of the frames. ventricle, similar to that noted on the preoperative examination. The injection of 2 cc of indocyanine green dye through an indwelling left atrial catheter confirmed that the echo-free space was due to left atrial prolapse (Fig. 7).

Discussion

Limitations of M mode echocardiography: Echocardiography is an excellent technique for detecting abnormal accumulations of pericardial fluid.[5–8] M mode echocardiographic tracings of good technical quality have detected fluid accumulations as small as 15 cc.[13] However, improper echocardiographic control settings can obscure the diagnosis of much larger amounts of pericardial fluid.[7] In addition to false negative examinations, the narrow field of view of M mode echocardiography has led to false positive diagnoses of posterior pericardial effusion in the presence of left pleural effusion and also in mitral anulus calcification.[7] Extreme medial transducer augulation has been thought to produce an echo-free space behind the left ventricular posterior wall due to inclusion of an enlarged coronary sinus or one of the pulmonary veins in the ultrasonic beam.[7] The descending aorta was recently shown to create an isolated echo-free space behind the left ventricle.[11]

M mode echocardiography has proved reliable in the detection of left atrial enlargement.[1–4] However, because of its one dimensional character, the technique may produce erroneous estimates of left atrial size in the presence of asymmetric left atrial enlargement.[9,10] Indeed, measurement of the left atrium in two dimensions, one from the suprasternal area and one from standard precordial approach, has been reported to detect nonspherical left atrial shapes.[14] One case of the false positive diagnosis of pericardial effusion by M mode echocardiography in the presence of a huge left atrium was previously reported.[15] We have described three additional cases in which this diagnosis was confirmed by two dimensional echocardiography.

Role of two dimensional echocardiography: A large left atrium is frequently a result of mitral valve disease. An enlarged atrium does not commonly project behind the left ventricular posterior wall but, when present, it can mimic a posterior pericardial effusion on M mode examination. In our three cases the spatial orientation provided by two dimensional echocardiography permitted accurate recognition of portions of a hugely dilated left atrium that prolapsed behind the left ventricular posterior wall and resulted in the M mode findings.

In Case 1 with mitral insufficiency, a right anterior oblique left ventricular cineangiogram demonstrated contrast medium beyond the contours of the heart behind the left ventricle. This unexpected finding suggested the presence of a ventricular septal defect or false aneurysm of the left ventricle.[13,16] The two dimensional echocardiogram showed a huge left atrium that extended behind the left ventricle. The incompetent mitral valve allowed left atrial filling after the injection of dye into the left ventricle, which resulted in this unusual cineangiogram. In Case 2 with mitral insufficiency a right anterior oblique cineangiogram correctly identified left atrial prolapse. In Case 3 with mitral insufficiency the lateral projection of a biplane left ventricular cineangiogram easily visualized the prolapsed portion of a huge left atrium.

We conclude that two dimensional echocardiography should be utilized in the presence of a large left atrium to look for left atrial prolapse when isolated echo-free spaces are noted behind the left ventricular posterior wall on M mode echocardiography. Also, left atrial prolapse may result in left ventricular angiographic findings suggesting a ventricular septal defect or a false aneurysm of the left ventricle in the single plane right anterior oblique projection.

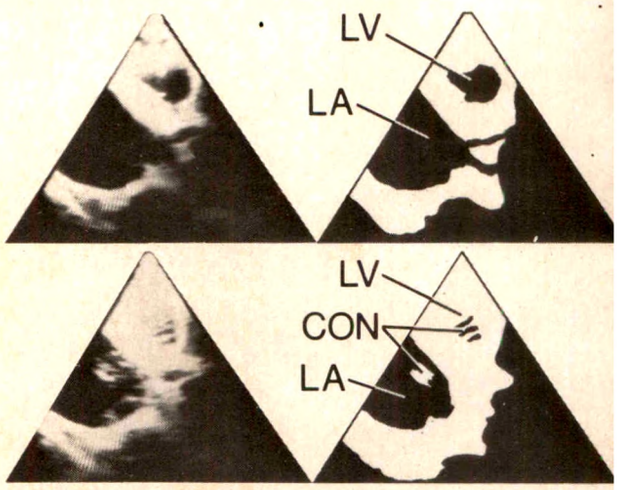

FIGURE 7. Case 3. Two dimensional echocardiographic transvers sections through the left ventricle (**left**) and an artist's reconstruction (**right**). The **upper panel** reveals a huge echo-free space posterior t the left ventricle (LV). The **lower panel** is the same view after injectio of indocyanine green dye directly into the left atrium. It reveals echo cardiographic contrast solution (CON) within the prolapsed left atriur (LA) and the left ventricle.

Acknowledgment

We gratefully acknowledge the assistance of Martin O'Neil, MD for allowing us to study his patient (Case 3) in th immediate postoperative period and the secretarial assistanc of Nina Kaye Gingerich.

eight cardiology greats
from Little, Brown

Johnson, Haber, & Austen
THE PRACTICE OF CARDIOLOGY (1980)

"Written by a team from the Massachusetts General Hospital, [the book] consists of a collection of essays that cover all the practical aspects of diagnosis and management. The book has been written for clinicians and is well organised for that purpose... it is well-written, and the authors are not afraid to identify themselves and their opinions... this excellent textbook has much to recommend it over larger volumes..."
—Lancet

1,312 pages, illustrated. #469459, $59.95

Cohn
DIAGNOSIS AND THERAPY OF CORONARY ARTERY DISEASE (1979)

"Dr. Cohn and his contributors have rendered an important service to patients with ischemic heart disease and to all who are involved in their medical evaluation and treatment, for the book is a timely, well-written, and informative summary of contemporary diagnostic and therapeutic approaches to the management of this important cardiovascular problem."
—New England Journal of Medicine

509 pages, illustrated. #150320, $32.50

Abel & McCutcheon
CARDIOVASCULAR FUNCTION: PRINCIPLES AND APPLICATIONS (1979)

"The text is a readable, informative, and thorough summary of cardiovascular physiology. It provides an excellent scientific basis for the understanding of clinical cardiology. I would recommend cover-to-cover reading for any cardiology fellow."
—New England Journal of Medicine

424 pages, illustrated. #001902, $35.00

Johnsrude & Jackson
A PRACTICAL APPROACH TO ANGIOGRAPHY (1979)

"This handsomely presented volume on angiography consists of 22 chapters devoted initially to the presentation of fundamental information in the field, followed by a detailed discussion of specialized techniques requiring various degrees of expertise.... This monograph can unqualifiedly be recommended...." *—Journal of the American Medical Association*

579 pages, illustrated. #469807, $48.50

Alpert & Rippe
MANUAL OF CARDIOVASCULAR DIAG OSIS AND THERAPY (1980)

This concise, practical manual is unbeatable for fast, reliable protocols on the diagnosis and management of patients with cardiovascular disease. It includes the diagnostic characteristics of each disease entity and hard-to-find information on exercise as it relates to heart disease, psychological effects of cardiac disease, and non-cardiac surgery in patients with heart disease.

384 pages, spiralbound. #035025, $12.95

Alpert & Francis
MANUAL OF CORONARY CARE, Second Edition (1980)

"This handbook is a practical, timely, extremely valuable, quick reference to the care of the acute cardiac patient. It is clearly more comprehensive and scholarly than its counterparts in other areas of acute care medicine, yet it doesn't sacrifice brevity and clarity in accomplishing this."
—Richard Jerauld, M.D., Chief Medical Resident, Wadsworth Hospital Center, Los Angeles (about the first edition)

Now available in a totally revised, expanded second edition that presents the most reliable, current, and concise coronary care information available!

174 pages, spiralbound. #035033, $11.95

Behrendt & Austen
PATIENT CARE IN CARDIAC SURGERY, Third Edition (1980)

"This book is the best bargain I know of in medical literature. Compressed into 179 pages is an astonishing amount of highly effective material.... This book should be in every critical care unit and in every senior resident's pocket, medical or surgical, cardiac or not." *—Chest* (about the second edition)

Approx. 250 pages. Spiralbound, #087564, $12.95

Hillis, Ormand, & Willerson
MANUAL OF CLINICAL PROBLEMS IN CARDIOLOGY: WITH ANNOTATED KEY REFERENCES (1980)

This indispensable manual is a time-saving guide to the best in cardiology literature. It presents succinct summaries of the pathophysiology, differential diagnosis, and management of approximately 100 common cardiac disorders. Each summary is followed by a selection of annotated references to the most important classic and current books and journal articles on the entity discussed.

315 pages, Spiralbound. #364002, $12.95

ELEVENTH BETHESDA CONFERENCE: Prevention of Coronary Heart Disease*

September 27, 28, 1980, Heart House, Bethesda, Maryland

Sponsor: American College of Cardiology
Co-Sponsors: American Heart Association

Center for Disease Control
(Department of Health and Human Services)

National Heart, Lung, and Blood Institute
(National Institutes of Health, Department of Health and Human Services)

Preface

The focus of this Bethesda Conference on the Prevention of Coronary Heart Disease was the role of physicians. From its inception, this orientation was explicitly defined by the convenor and the co-sponsors—the American College of Cardiology, the American Heart Association, the National Heart, Lung, and Blood Institute and the Center for Disease Control. The concept was that physicians had already contributed much to the coronary heart disease prevention effort and have the potential to do much more; therefore, more attention should be given to realizing their full potential, especially in concert with allied health professionals.

Correspondingly, it was agreed that the main concern of this Conference was *not* the role of voluntary or official agencies or of lay organizations and groups in the community—as important as is their contribution. Further, it was also agreed that this Conference was not to undertake a systematic review once again of the data base and scientific foundation of the effort to prevent coronary heart disease, for example, in regard to modifiable lifestyles (eating, drinking, smoking, exercise patterns) and other risk factors; this had been done repeatedly by competent and representative groups o experts in the 1970s—for example, for the Americar Heart Association, the Inter-Society Commission fo Heart Disease Resources, the National Heart, Lung, and Blood Institute and other official agencies—includin reports issued this year and last. The recommendation of these groups were accepted as scientific foundation for the Conference, that is, reasonable and sound bes judgment consensus assessments of currently extan knowledge and its practical implications, with the rec ognition that varying emphases and dissenting view existed, that relevant research was ongoing, that mor research was needed and that with further informatio and experience preventive approaches would evolve an advance. In this context, there was also the clear rec ognition that physicians could and should contribut much more to the coronary prevention effort now an in the years immediately ahead. The Conference aime to achieve a consensus—in the tradition and spirit o Bethesda Conferences—to this end.

THE STEERING COMMITTE

* The recommendations set forth in this report are those of the Conference participants and do not necessarily reflect the official position of the American College of Cardiology. This study was supported in part by NIH contract 263-80-C-0510 from the National Institutes of Health of the Department of Health and Human Services.

Address for reprints: American College of Cardiology, Heart House, 9111 Old Georgetown Road, Bethesda, Maryland 20014.

Opening Statement

JEREMIAH STAMLER, MD, FACC

On behalf of the American College of Cardiology, the initiator of this Bethesda Conference, and its co-sponsors—the American Heart Association, the National Heart, Lung, and Blood Institute and the Center for Disease Control—it is a great honor and pleasure for me to open this Bethesda Conference on the Prevention of Coronary Heart Disease. As you all know, in the decade of the 1970s substantial progress was registered in controlling the epidemic of premature coronary heart disease in the United States. Our mortality rates declined more than 25 percent. We set the pace for other countries in this regard. However, our rates of sickness, disability and death from this modern plague still remain high, among the highest in the world. Hence this Conference.

The focus of this Conference is the role of the physician in the effort to make substantial further advances in the prevention of coronary heart disease. Clearly, physicians have already contributed significantly Witness the millions of people with high blood pressur whose condition has been detected, evaluated, treate and brought under long-term control. Witness th millions who on the advice of their physicians hav changed their eating habits to control hyperlipidemia obesity, hypertension, diabetes mellitus—the majo coronary risk factors. While our profession has alread done much, clearly there is a great deal remaining to b done. In the tradition of the Bethesda Conferences, w are here to arrive at a consensus as to the most effectiv ways to go forward with this effort in the 1980s. For thi purpose, it is excellent that we have here today repre sentatives of the key medical and health professiona organizations whose members must do the job. All of u are particularly gratified with your response to our in vitation and we especially extend a warm welcome to a of you.

The Mission of Prevention

ROBERT O. BRANDENBURG, MD, FACC

On behalf of the American College of Cardiology, and its co-sponsors, the American Heart Association, the Center for Disease Control, and the National Heart, Lung, and Blood Institute, we are very pleased that you are here. We are delighted that we can serve as the site for this important conference.

Four years ago, the Long Range Planning Committee of the American College of Cardiology spent many hours developing a mission statement. I'd like to review it with you.

The mission of the College is to ensure optimal care for persons with cardiovascular disease or the potential fc developing it; and ultimately, through appropriate educa tional and socioeconomic activities, to contribute signifi cantly to the prevention of cardiovascular disease.

It is difficult to imagine a Conference more appro priate to this mission than the one about to begin. As clinician I recognize that preventive cardiology pro grams are difficult to execute. It is my hope and ex pectation that, as a result of this Conference, the prac tice of preventive coronary artery disease programs wi be expedited and advanced.

The Opportunity and the Task

THOMAS N. JAMES, MD, FACC

No one—certainly no one here—is likely to speak against the value of preventing disease. The American Heart Association is fully committed to doing everything possible to prevent heart disease, and we share with many others a great pride in seeing what has been done in preventing rheumatic heart disease. At this meeting, Dr. Stamler will lead and stimulate wide-ranging discussions on what physicians can do to prevent coronary heart disease. Because this subject is so important and timely, and because the participants were invited on the basis of their considerable professional stature, one may predict that your report will be widely read and influential. As you deliberate these two days, would you please keep in mind these few points:

1. While death from coronary disease has steadily decreased for more than 10 years, no one knows whether the incidence and severity of coronary disease in this period have increased, decreased or stayed the same.
2. About 9 of 10 patients with hypertension, a major risk factor for coronary disease, have essential hypertension, the cause of which is unknown.
3. Prevention and reduced risk are not the same thing. Be careful to distinguish between them because your credibility of statement is at stake.
4. As a physican you advise patients one at a time. And data from large population studies may or may not apply to the individual person. Remember the individual.

You have a remarkable opportunity, and I'm confident that you are up to the task. I wish you every success in your work.

The Physician and Prevention

ROBERT I. LEVY, MD, FACC

The National Heart, Lung, and Blood Institute and the Center for Disease Control are delighted to be the federal sponsors for this program. Disease prevention and health promotion are major and growing concerns of the Center for Disease Control. Today, representing the Center with us is Mr. Horace Ogden, director of the Center's Bureau of Health Education.

The commitment of the National Heart, Lung, and Blood Institute to prevention is long-standing. That is the ultimate aim, the ultimate objective of all our work in all the diseases we face; it is clearly mandated in our legislation. And as I am sure you have all heard me say again and again, we think of prevention throughout the biomedical research spectrum.

We think of our aim of prevention when we talk about knowledge acquisition; more work that has to be done, as Dr. James has indicated, in etiology, pathophysiology. We think of prevention as an objective in our knowledge validation activities, certainly our multicenter clinical trials that are underway now, testing the risk factor hypothesis. And we think of prevention in our many areas in knowledge translation and knowledge dissemination to the community.

Dr. Stamler has already spoken of, and the next speakers will clearly talk about, the importance and potential of coronary disease prevention. Coronary artery disease is the major killer disease today. It is coming under control, if we look at mortality figures, but it still is responsible for more than twice as many deaths as any other disease.

Coronary artery disease is caused predominantly by a silent process we call atherosclerosis, a process that all too frequently manifests as its first sign sudden death—a flag to all of us that prevention has to be our goal. To wait to palliate clearly would be to wait too long.

Dr. Stamler has already mentioned that 2 years ago we had a conference to examine the cause or nature of the decline in cardiovascular disease. It was quite clear from the facts at hand at that conference that the decline was real. However, as Dr. James suggests, we could not agree on the cause of the decline. We could not quantitatively agree how much had come because of the changes in lifestyle and habits, in smoking and blood pressure and nutrition and exercise that the public had undertaken in the last decade; and how much we could attribute to improved medical care and better treatment. But I think what did come out of that conference

was a consensus that prevention had played a role, and a consensus that preventive activities should and must be intensified in the future.

If I had any doubt about the role of the physician in prevention, that doubt has completely disappeared as I have witnessed the success of the National High Blood Pressure Education Program in which physicians have taken the lead from the first. Surveys continue to show us that the public feels strongly that medical advice about changes in lifestyle habits would be most positively responded to if it came from their physicians. We also learned from the public that they feel that less than half of their physicans spend any considerable time providing them with information dealing with prevention. If I had to give a challenge to this conference, I would list four charges: (1) This conference needs to promote the concept that prevention is an integral and beneficial part of the practice of medicine. (2) It needs to identify areas in which the physican can make significant contributions. (3) It needs to provide examples or guidance to the physician in various settings. And finally (4) it needs to motivate those who are not now actively engaged and to reinvigorate and reinforce those who are.

There have been examples of successful programs in which government has disseminated information to physicians. Some of these have resulted in improved health care. However, when it comes to advising physicians on how to practice, I don't have to say that government involvement is usually not appreciated.

Therefore, it is important that this Conference, and the messages that it will develop, is the product of practicing physicians talking to physicians. It is gratifying to me that this conference is the brainchild of the American College of Cardiology, and that the bulk of the organizations participating are physician-oriented. More than gratification: it gives me great optimism that the lessons we learn during these next 2 days won't be left in Bethesda, but will reach those who can and should put them into practice.

The Concept of Bethesda Conferences

WALTER H. ABELMANN, MD, FACC

On behalf of the Bethesda Conference Committee of the American College of Cardiology, I thank you for participating in this Conference. Allow me to say a few words about the concept of Bethesda Conferences and about their methodology. The College recognizes that there are important topics and areas of concern to the profession it represents on which there is no general agreement. Yet, in many of these areas, a position and often action on the part of the physician and society are mandated and guidance is needed.

The Bethesda Conferences are designed to step into this difficult zone, by providing recommendations based on the consensus of a broadly representative sample of experts. The method we use to do this is the so-called Delphi method. The Delphi method was developed over 25 years ago at the Rand Corporation as a method of arriving at consensus about long-range forecasting as an aid to planning. This method underlies the Bethesda Conferences, introduced by the College in 1966. In its traditional form, the method consists of sending a questionnaire to a group of experts and then making a synthesis for further consideration. This process may be repeated as necessary. The strength of this method of predicting future developments lies in the selection of a broad sample of experts and the provision of opportunities for anonymous expression of views as well as for interchange of views and ideas.

Thus, each one of you is here as an expert on some aspect of our topic, and your individual contribution is essential to the validity of the process. If the topic of our deliberation were not in some flux and beset with uncertainty, we would not have assembled for this Conference. Therefore, the consensus document that we hope will result, while representing the best guidance we can give at this time, is not meant to stand up in its entirety in the face of future research and discoveries. What should stand up for some time to come is the physician's approach to his or her responsibility toward the patients and the population he or she serves with regard to preventive cardiology, that is, the manner in which he or she can and should discharge this responsibility.

I would like to charge this Conference, then, with the task to focus upon this aspect of the problem, irrespective of such disagreement as may arise over the relative strength and importance of given risk factors for coronary heart disease. Whereas the conclusions and recommendations of this Conference will stand on their own and do not represent a formal position of the American College of Cardiology, the College does accept responsibility for conducting this consensus conference in the tradition of excellence set by past Bethesda Conferences.

The Scientific Foundation for Prevention of Coronary Heart Disease

THEODORE COOPER, MD, FACC

We are in an age of preoccupation with numbers—so-called data. Ideas that cannot be quantified have little or no acceptance. Truth is revealed by a statistical formula, even though the science of biostatistics is acknowledged to be evolving. We are still trying to fit poorly understood distributions into mathematical concepts based on understood distributions. It is therefore important, to recognize the factors that influence appreciation or evaluation of studies. An acute illness presents relatively little problem compared with a chronic illness such as coronary heart disease. Yet, we seem committed to the view that the numbers are the way to paradise.

For the public official, for the advisors to the public official, for the consumer activist, for the medical liability lawyer, paradise is having what is called a "definitive study" on whether eating fewer eggs will prevent coronary heart disease. For the practicing physician, definitive studies are also of help, if he or she could accept what is meant by definitive. I would guess that the most distressing thing about studies today, for the practicing doctor, is to try to interpret studies that claim a 20 to 25 percent difference between control and treated groups, statistically significant to a given power like 0.001. Does that mean that only some will benefit? Or something else?

Some of you might scoff at such a question. However, such issues are at the heart of physician acceptance of statistical studies. I have often been asked why seemingly competent physicians would adopt suspect practices and not accept the revealed truth of certain studies, particularly government-sponsored studies, which most of them are. And I have often been told by practitioners that the problem with the studies is that the people who did them, particularly the people who designed them, don't know the first thing about patients or disease management.

Recent Decline in Coronary Mortality

I mention these points because it was my assignment to review the scientific foundations of the preventive approach to management of coronary heart disease. I have reviewed—as you have—a wide variety of documents and data from epidemiologic studies and clinical trials on various factors believed operative in the pathogenesis of the disease. It is particularly pleasing to be able to say that total mortality has been declining, not just mortality due to heart disease or strokes. In fact, if one were not discriminating one might caution about pushing programs too hard; it doesn't seem too far to zero. But discriminating we must be; it is perfectly clear that there is still a formidable job to be done and, despite truly impressive gains over the past several years, we must press on.

In order to present proposals that are designed for further reduction in mortality, we should probably understand, and perhaps agree on, what the basis of the recent improvement is or was. It seems that study of the same data made available to you and me left the experts somewhat confused or at least with different viewpoints. However, I was reassured to learn that they thought the decline was real. Results have been presented in various publications and forums supporting the view that modifying "the risk factors" has had something to do with the trends. The consensus is quite strong that cigarette smoking is a thing to avoid if you don't smoke—or to stop if you do. But there are other factors on which the agreement is not so clear from epidemiology and clinical trials on various factors believed operative in the pathogenesis of the disease.

The Role of Risk Factors

There are some studies not included in your program packets that bear importantly on our task. These studies address the question of where people get their information about health and medical care and what they believe. On many occasions, when urging physicians to "*do more prevention,*" they point out that "everybody knows these things are not settled." The scientific foundation for this kind of approach must include a variety of other approaches of inquiry. An important set of studies that asks people where they get their information, and what they think is reliable and what they think is not reliable, is extremely important. For example, the recent discussions about cholesterol and the American diet that resulted from the release of a report from the National Academy of Sciences left some people, including some doctors, confused and annoyed. I mention this here not to open wounds or to join the debate but only to indicate the importance of an important observation. What do people think is a reliable source of useful medical and health information? Their doctor—of course! Not the government.

When I was a public official and I would speak to lay audiences about good health practices and make an assertion backed up by a panel of experts who had evaluated complex studies, the people would go to their own doctors and ask, "Is that right?" I am somewhat

reticent to present to this audience the data from Framingham or the Diet Heart Study, or the various Veterans Administration studies on diet or hypertension, or the Hypertension Detection and Followup Program or the studies of Dr. Stamler and his group and so on. You probably know them better than I. So I shall not present the specific data. I shall comment on the foundation these studies offer. I believe they mean something. I believe they indicate that attention to the risk factors should have an influence on the development of the disease. I do not believe that it is the entire answer to prevention. But in the current state of the art it forms a basis for some specific approaches that should be utilized by practitioners. Furthermore, I am confident that changes will occur, for in fact, as you will hear in the next presentation, change has occurred.

It is appropriate to ask if the scientific foundation is adequate. Having said I believe that the studies are meaningful, I might be expected to say that they are adequate. The foundation is an adequate basis for action, but certainly not adequate to reach a decision that no further studies are needed. More studies—lots more—are required. But we can take action on less than complete or perfect information. There are several reasons to support this position. First, there are data to support the view that in some persons weight control, dietary management, a rational program of physical activity, lowering elevated blood pressures, controlling diabetes, cessation of cigarette smoking and avoiding excessive alcohol consumption will improve the chances of avoiding clinical coronary heart disease. Second, we know that virtually all of these measures have little or no serious risk of harm to the person—when properly instituted. Third, the cost of the required modifications of this life style or therapeutic interventions is modest. Fourth, the technical demands of the program for the physician, other health professionals or people themselves are relatively simple. So my point then is that the programs that require change in what people do and often enjoy doing—changes that can run contrary to well ingrained social and economic aspirations—will have to have the imprimatur of the personal health guru, the doctor.

I am delighted to see the acceptance of the need to pay attention to the young. Studying the young has special problems. Some of the problems are cultural and ethical. But the greatest deficit is that there are too few studies. However, the interests of investigators are changing and the notion is gaining credibility that chronic cardiovascular disease may begin early in life. And this is a most important fact to accept in the design of a program of prevention.

I am also pleased to note that genuine studies support the notion that prevention can be effectively practiced at the work site. I have resisted talking about high blood pressure as the end-all and be-all of the field. However, the recent approach to preventive education and control in this facet of the problem of coronary heart disease has been rewarding indeed. High blood pressure programs have provided excellent demonstrations that prove preventive approaches will work. It has been particularly gratifying to me to see the plethora of good results from the studies and control programs alike, although the experts are not unanimous in their approach and analysis of the data. The Hypertension Detection and Followup Program must be looked upon as an enormous contribution of great importance to the field.

Long-term clinical studies are difficult and expensive to carry out. We are learning how difficult it is to design studies that can ensure success. We are not even certain that we know what a so-called negative result means—much less what a mixed or marginal answer means. Lifestyles and habits are changing and practices are changing; hence, reference points are changing. Therefore, with the best of intentions and thoroughness of design, our current technology will often fall short of answering the question, and we must be wary of concluding that a big indecisive study means that it doesn't work. So I again call for common sense as well as for more data in reaching judgments about what to recommend for maintaining well-being.

Behavioral and Social Factors

Finally, one area of risk factors is receiving too little attention. Indeed, some might feel that these factors should not be classified as risk factors. I refer to behavioral and social factors. I believe that studies in this area are important for two principal reasons. First, they offer possibilities—both direct and indirect—of understanding pathologic mechanisms of coronary heart disease and its expression. Second, they are relevant to patient adherence to programs or what is usually called compliance.

Here is an area that is particularly important for constructing an action program for physicians. Both patient and physician become discouraged in seeing no results. We are a "fast result" society. What we are asking people to do is to look beyond the usual short term, to generation-long and lifelong practice modification.

There is a tendency to group all or most of the things directly related to prevention of coronary heart disease as elements of lifestyle—such activities as eating, smoking, drinking, working, playing, and so on. In a very real sense we are asking people to change many of the things they do that have been familiar cultural, social and religious practices. Eating is a prime example. We could very easily fall prey to the notion that the purpose of eating is nutrition only. As you well know, it is much more than that. There is indeed much more to life than just living. So we must guard against predicting disaster from the pulpit, and we must try not to legislate lifestyle out of frustration with the rate of progress we have seen.

We must educate not only patients, but also physicians and society as a whole. We look toward this Bethesda Conference to produce a program of specific steps to follow to prevent disease.

Primary Prevention of Coronary Heart Disease: The Last 20 Years

JEREMIAH STAMLER, MD, FACC

My assignment is to review developments and experiences over the last 20 years in the effort to achieve the primary prevention of coronary heart disease in the United States. First, I will briefly review the development of policy for the health professions and the general public. Then I will describe the changes that have taken place in lifestyles and lifestyle-related risk factors in our population. Finally, I will present data on the decline in mortality from coronary heart disease over the last decade.

Development of Public Policy

To the best of my knowledge, the initial call for an effort to prevent coronary disease was the "*Statement on Arteriosclerosis, Main Cause of 'Heart Attacks' and 'Strokes,'* " co-authored in 1959 by Paul Dudley White, Louis N. Katz, Samuel Levine, Irvine H. Page, Howard B. Sprague, Frederick J. Stare, Irving S. Wright and myself.[1] This was an initiative of a group of individuals, cardiologists and cardiovascular researchers, not of an organization, voluntary or official. This brochure was circulated in hundreds of thousands of copies by the National Health Education Committee, with the support of Mrs. Mary Lasker, whose name looms large in regard to progress in cardiovascular research and control. This document, written almost a quarter of a century ago, called attention to all of the traits—hypercholesterolemia, cigarette smoking, hypertension—later designated major risk factors, plus overweight and a positive family history of premature hypertensive and atherosclerotic disease.

A year later, in 1960, the American Heart Association issued its first statement on cigarette smoking and cardiovascular disease.[2] The committee drafting that report was chaired by my mentor and chief, Dr. Louis N. Katz, also a co-author of the just cited *Statement*. He and Paul Dudley White, Samuel Levine, Irvine Page, Howard Sprague, Irving Wright—leaders among the older generation of cardiologists and cardiovascular investigators—were statesmen. They all were deeply concerned to assure that the fruits of research were made available as rapidly and effectively as possible to the profession and the public.

In 1961, the American Heart Association issued its first statement on diet and coronary heart disease,[3] calling attention both to the matter of lipid composition of the diet—avoidance and correction of high intake of saturated fat and cholesterol—and of calorie imbalance and consequent obesity. As you all know, the American Heart Association has at intervals updated these documents.[4–7]

In 1964, the landmark *Report of the Advisory Committee to the Surgeon General on Smoking and Health* was published,[8] probably with the first clear lead from the federal government relating to the effort to prevent coronary heart disease.

In 1970, the Inter-Society Commission for Heart Disease Resources issued its *Report on the Primary Prevention of the Atherosclerotic Diseases*.[9] It, like its predecessors, was thoroughly documented with references to research studies delineating the scientific foundation of the prevention effort. Figure 1 presents the succinct summary the Inter-Society Commission distilled of its recommendations: first and foremost, the need for a strategic emphasis on primary prevention as long-term national policy; then the effective implementation of that strategy, in order to accomplish changes in diet to prevent or control hyperlipidemia, obesity, hypertension and diabetes; the elimination of cigarette smoking; and the pharmacologic control of elevated blood pressure where indicated. After that summary of its approach, the *Report* gave detailed recommendations on implementation. The Inter-Society Commission—established as a result of federal legislation and at the request of the Assistant Secretary for Health (the Surgeon General)—was made up of representatives of all the key medical and health professional organizations concerned with this challenge, including those represented here today.

In the next year, 1971, both the White House Conference on Nutrition and the Task Force on Arteriosclerosis of the National Heart and Lung Institute also addressed these matters and made available to the health professions and the public similar summary recommendations, in agreement with those already noted.[10,11]

In 1973 there was another important development: the official assumption of federal responsibility, at the Cabinet level, for control of a major unsolved mass public health problem, high blood pressure—with the launching by the Secretary of Health, Education, and Welfare of the National High Blood Pressure Education Program, under the aegis of the National Heart, Lung, and Blood Institute.[12]

RECOMMENDATIONS FOR PRIMARY PREVENTION
OF THE ATHEROSCLEROTIC DISEASES
INTER-SOCIETY COMMISSION FOR HEART DISEASE RESOURCES, 1970

"The Commission recommends that a strategy of primary prevention of premature atherosclerotic diseases be adopted as long-term national policy for the United States and to implement this strategy that adequate resources of money and manpower be committed to accomplish:

"Changes in diet to prevent or control hyperlipidemia, obesity, hypertension and diabetes.

"Elimination of cigarette smoking.

"Pharmacologic control of elevated blood pressure."

FIGURE 1. Recommendations for primary prevention of the atherosclerotic diseases. Inter-Society Commission for Heart Disease Resources, 1970.

In the late 1970s the Select Committee on Nutrition and Human Needs of the U.S. Senate presented a set of dietary goals for the United States, emphasizing improvement in both the lipid and carbohydrate composition of the diet (Fig. 2).[13] That report also called attention to the matter of avoiding and correcting calorie imbalance and consequent obesity and high sodium intake. It also succinctly indicated reasonable approaches to food selection to achieve these dietary goals (Fig. 3). Like all such recommendations, these were also concerned to aid Americans in maintaining and even improving intake of all essential nutrients.

Implicitly or explicitly, they are also dedicated to helping Americans to continue—in a healthier way—to enjoy one of life's pleasures, the pleasure of eating, for example, by taking tips from Mediterranean and Far Eastern eating styles. In the course of this effort, the American Heart Association produced a national best seller, the *American Heart Association Cook Book*, now in its third edition.[14]

In 1979, the American Diabetes Association updated its earlier reports, presented jointly with the American Dietetic Association, on principles of nutrition and dietary recommendations for individuals with diabetes.[15–17]

At the turn of the decade, the Report of the Surgeon General, *Healthy People—A Report on Health Promotion and Disease Prevention*,[18] dealt comprehensively with the major present-day challenges to the health of the American people at each stage of life, including those of better lifestyles from childhood on—better habits in regard to eating, drinking, smoking and exercise—to help control the epidemic of coronary heart disease, and other major chronic disease problems as well. The Institute of Medicine of the National Academy of Sciences contributed importantly in the devel-

DIETARY GOALS FOR THE UNITED STATES

1. TO AVOID OVERWEIGHT, CONSUME ONLY AS MUCH ENERGY (CALORIES) AS IS EXPENDED; IF OVERWEIGHT, DECREASE ENERGY INTAKE AND INCREASE ENERGY EXPENDITURE.
2. INCREASE THE CONSUMPTION OF COMPLEX CARBOHYDRATES AND "NATURALLY OCCURRING" SUGARS FROM ABOUT 28 PER CENT OF ENERGY INTAKE TO ABOUT 48 PER CENT OF ENERGY INTAKE.
3. REDUCE THE CONSUMPTION OF REFINED AND PROCESSED SUGARS BY ABOUT 45 PER CENT TO ACCOUNT FOR ABOUT 10 PER CENT OF TOTAL ENERGY INTAKE.
4. REDUCE OVERALL FAT CONSUMPTION FROM APPROXIMATELY 40 PER CENT TO ABOUT 30 PER CENT OF ENERGY INTAKE.
5. REDUCE SATURATED FAT CONSUMPTION TO ACCOUNT FOR ABOUT 10 PER CENT OF TOTAL ENERGY INTAKE; AND BALANCE THAT WITH POLY–UNSATURATED AND MONO–UNSATURATED FATS, WHICH SHOULD ACCOUNT FOR ABOUT 10 PER CENT OF ENERGY INTAKE EACH.
6. REDUCE CHOLESTEROL CONSUMPTION TO ABOUT 300mg. A DAY.
7. LIMIT THE INTAKE OF SODIUM BY REDUCING THE INTAKE OF SALT TO ABOUT 5 GRAMS A DAY.

FIGURE 2. Dietary goals for the United States. Select Committee on Nutrition and Human Needs of the U.S. Senate.

CHANGES IN FOOD SELECTION AND PREPARATION
TO ACHIEVE THE U.S. DIETARY GOALS

1. INCREASE CONSUMPTION OF FRUITS AND VEGETABLES AND WHOLE GRAINS.
2. DECREASE CONSUMPTION OF REFINED AND OTHER PROCESSED SUGARS AND FOODS HIGH IN SUCH SUGARS.
3. DECREASE CONSUMPTION OF FOODS HIGH IN TOTAL FAT, AND PARTIALLY REPLACE SATURATED FATS, WHETHER OBTAINED FROM ANIMAL OR VEGETABLE SOURCES, WITH POLY–UNSATURATED FATS.
4. DECREASE CONSUMPTION OF ANIMAL FAT, AND CHOOSE MEATS, POULTRY AND FISH WHICH WILL REDUCE SATURATED FAT INTAKE.
5. EXCEPT FOR YOUNG CHILDREN, SUBSTITUTE LOW–FAT AND NON–FAT MILK FOR WHOLE MILK, AND LOW–FAT DAIRY PRODUCTS FOR HIGH FAT DAIRY PRODUCTS.
6. DECREASE CONSUMPTION OF BUTTERFAT, EGGS AND OTHER HIGH CHOLESTEROL SOURCES. SOME CONSIDERATION SHOULD BE GIVEN TO EASING THE CHOLESTEROL GOAL FOR PRE–MENOPAUSAL WOMEN, YOUNG CHILDREN AND THE ELDERLY IN ORDER TO OBTAIN THE NUTRITIONAL BENEFITS OF EGGS IN THE DIET.
7. DECREASE CONSUMPTION OF SALT AND FOODS HIGH IN SALT CONTENT.

FIGURE 3. Recommended changes in food selection and preparation to achieve the U.S. dietary goals. Select Committee on Nutrition and Human Needs of the U.S. Senate.

. opment of this report.[19] Early this year, the U.S. Department of Agriculture and the U.S. Department of Health, Education and Welfare (now Health and Human Services) published the colorful folder, *Nutrition and Your Health: Dietary Guidelines for Americans.*[20]

Early this year also, the Committee on Dietary Allowances, Food and Nutrition Board, National Academy of Sciences, in the ninth edition of its *Recommended Dietary Allowances,*[21] presented guidelines on desirable amounts and proportions of dietary fat and carbohydrate: not more than 35 percent of calories from total fat, particularly in diets below 2,000 calories; greater reduction in fats containing predominantly saturated fatty acids, such as those from animal sources, than in vegetable fats containing unsaturated fatty acids; an upper limit of 10 percent of dietary energy as polyunsaturated fatty acids; reduced intake of refined sugars; maintenance or even increase in complex carbohydrate; for many individuals a reduction in alcohol consumption. The comment was made, "These recommendations for desirable types and amounts of dietary fat and carbohydrate do not entail radical changes in eating habits and could be accomplished with the United States food supply. Indeed many individuals normally have dietary practices that follow this pattern. The American Heart Association and the Working Party of the Royal College of Physicians of London believe that these dietary recommendations, in conjunction with measures to decrease other risk factors, have a reasonable hope of being beneficial." [21] A few months later, another Food and Nutrition Board report[22]—while advising dietary measures to control obesity (including lower intake of fats, oils, sugars and alcohol) and moderation in salt intake—made no recommendations about ingestion of saturated fats, and ". . . no specific recommendations about dietary cholesterol for the healthy person." [22] This statement, given wide publicity, led to extensive discussion and debate in the general press and before Congress, since it was rightly regarded as at variance on the matter of dietary lipids with conclusions and recommendations of expert committees over the last two decades. A detailed scientific critique of this report is available.[23]

Subsequently, the American Heart Association completed its report on *Nutrition Education of the Young,* and its updated general statement on *Risk Factors and Coronary Disease.*[24,25] The first of these reaches to a key issue and a central concern of this Conference: *primary* habit formation and the development of healthy lifestyles from early childhood on. The second serves as a key contemporary statement of the scientific foundations of this Conference.

Clearly, while there are dissenting views,[22,26] we have effective consistent public policy leads, developed by expert groups and responsible organizations over 2 decades, reflecting a rich mine of research information and a broad consensus in the scientific, professional, voluntary and official communities. And, in fact, similar position statements are available from expert groups in other countries experiencing the epidemic of coronary heart disease, and from the World Health Organization and the International Society and Federation of Cardiology (both represented here).[27–36]

May I add finally that we can be proud—in a healthy, nonchauvinistic way—that we in the United States have generally given the lead and set the pace in the development of public policy on the primary prevention of coronary heart disease.

TABLE I

Trends of Food Products Available for per Capita Annual Consumption, U.S.A., 1950–1978

Product	1950	1960	1970	1974	1978	% Change 1950 → 1978

*lb/person per year. † Total is by fat content, individual items are by actual weight.

Changes in Lifestyle and Related Risk Factors

The development of public policy has been steady and progressive over these 20 to 25 years. But the resources for dissemination have been modest. What about the American people? Have they "heard the message" and acted on it?

Eating patterns: Intriguing data are available from a 1976 U.S. Department of Agriculture survey.[37] It dealt with whether Americans have recently changed their eating styles because of health concerns. About half of a random sample of the population replied in the affirmative, indicating they had done so either to alleviate existing health problems or to avoid potential ones. Some stated they had done so on advice of their physicians, others on their own. The reasons were as we would expect: identification of such problems as hyperlipidemia, obesity, hypertension and diabetes, with diet change instituted to help control these. In addition, a substantial number of people reported modifying their diets for general public health and preventive medicine purposes. Such changes were made more frequently in households of higher educational and income levels and where the adults were younger.

All this is, of course, reporting of self-described behavior. Are there "hard" data? Yes, and they are in several respects in keeping with these Department of Agriculture survey results. Thus, per capita consumption of eggs (the yolk is the single largest source of dietary cholesterol) has gone down steadily from its 1950 peak—down 30 percent by the late 1970s (Table I).[38–40] Per capita consumption of total milk fat solids has de-

clined by a like amount. At the same time—reflecting purchase at the supermarket of more and more fat-free and low-fat products (skim milk, 1 percent and 2 percent milk, low fat yogurt, ice milk, low fat cottage cheese)—consumption of nonfat milk solids has declined much less. And, over the decades, a remarkable change has occurred in the use of the visible fats (Table I, Fig. 4).[38–41] Since 1950, per capita consumption of lard—that is, pig fat—has gone down 80 percent and of butter, 55 percent, both reflecting continuation and acceleration of a decades-long downward trend. Margarine has come into increasing use. Its per capita consumption has doubled since 1950 alone and, in recent years, a sizable proportion of the total margarine is of the "soft" variety, that is, relatively low in saturated fats and high in unsaturated and polyunsaturated fats—a deliberate response of manufacturers and consumers to nutritional advice related to serum cholesterol reduction and prevention of coronary disease. Use of vegetable shortening has also increased, by 73 percent since 1950, and again there has been a change in composition, with an increasing proportion liquid, that is, relatively low in saturates and high in unsaturates. And, of course, all these vegetable fats—like all vegetable products—contain no dietary cholesterol. Finally, there has been a marked increase in use of vegetable oils, most of them, with the exception of coconut and palm oils, also relatively low in saturates and high in polyunsaturates. On the other hand, since World War II per capita consumption of meat—particularly beef—has gone up sizably, and the resultant increase in saturated fat and cholesterol intake has in part, but only in part, compensated for the sizable declines due to the trends in egg yolk, dairy fat, and the visible fats. Recently, initial data have become available from the U.S. Department of Agriculture 1977–78 Nationwide Food Consumption Survey involving 30,000 households. These include a comparison of 1965 and 1977 findings

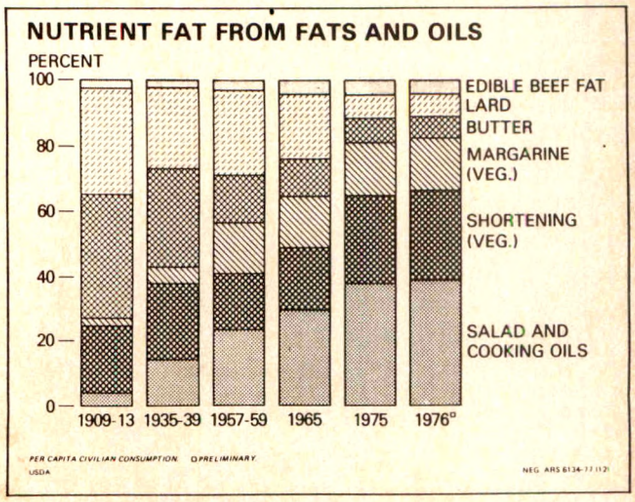

FIGURE 4. Nutrient fat from fats and oils (per capita civilian consumption). U.S. Department of Agriculture data.

(Table II).[42] In general, these are in agreement with the overall national food disappearance trends (Table I). However, a marked difference is to be noted in regard to beef, that is, decreased per capita intakes for young and middle-aged adults in the 1977 compared to the 1965 household survey, in contrast to the increase indicated by the disappearance data. (The Food Consumption Survey findings show a sizable increase per capita in beef consumption from 1965 to 1977 for male persons aged 15 to 18 and 19 to 22.) The household survey data indicate a considerable decline in percent of calories from total fat—from 45.1 percent in 1965 to 36.2 percent in 1977. The Department of Agriculture data therefore indicate that there have been modest but

TABLE III

Baseline Nutrient Intake Framingham, ND-HS and MRFIT Men

Nutrient	MRFIT (6,298 Men) 1977	Framingham (864 Men) 1970	ND-HS (1,196 Men) 1968
Calories per day	2,473	2,608	2,565
Protein (% of calories)	16.2	15.8	15.6
Carbohydrate (% of calories)	37.9	38.6	40.7
Alcohol (% of calories)	7.4	6.7	4.1
Total fat (% of calories)	38.4	39.0	40.4
Saturated fatty acids (% of calories)	13.9	15.0	15.6
Monounsaturated fatty acids (% of calories)	14.8	15.5	17.6
Polyunsaturated fatty acids (% of calories)	6.6	5.4	3.9
Cholesterol (mg/day)	450	530	533

MRFIT = Multiple Risk Factor Intervention Trial; 1977; ND-HS = National Diet Heart Study.

significant decreases in saturated fat and cholesterol intake by the American people.

The 1965 and 1977 household survey data also indicate a decreased intake of total calories by young adult and middle-aged American men and women. These data are intriguing in relation to the findings of the 1960–62 and 1971–74 Health Examination Surveys,[43] which indicate no change—possibly even a slight increase—in the sizable proportion of Americans who are grossly obese. Perhaps by the late 1970s, this situation was changed; this needs to be checked out.

One other trend merits attention: all the data indicate steady rises in per capita consumption of alcohol, and the epidemiologic evidence indicates a direct proportionality between average per capita consumption and prevalence of heavy drinking. This last phenomenon is of direct concern here because research in recent years has shown that heavy drinking is associated with higher prevalence rates of hypertension, independent of other traits related to risk of high blood pressure.[44–46] At this point it is also appropriate to note in passing that no data are available on trends of sodium consumption in our population.

Surveys of samples of the population indicate trends similar to those summarized earlier. Thus, comparison of the data on men volunteering for the Multiple Risk Factor Intervention Trial in the mid 1970s, and on men of the Framingham and National Diet-Heart Study surveyed a decade or so earlier indicate a modest decline in the 1970s in total fat, saturated fat and dietary cholesterol intake and a modest rise in intake of polyunsaturated fats (Table III).[47–49]

Serum cholesterol: In agreement with all these sets of nutritional data, surveys of the population indicate declines in average serum cholesterol levels toward more desirable goals (Table IV, Fig. 5).[50,51] Thus, repeated surveys in the late 1950s and early 1960s yielded average values ranging around 235 mg/dl for groups of middle-aged men. In the late 1960s and 1970s, the mean was 15 to 20 mg (about 7 percent) lower. Data are available indicating that these changes have been larger in the more educated than in the less educated strata of our population (Fig. 6).[51] Although these changes are still relatively modest, indicating that much remains to be done, they are all detectable in the population at large.

Cigarette smoking: The situation is similar in respect to cigarette smoking among adults, particularly those in the coronary-prone years from the 4th decade of life on. The prevalance of smoking in our population, at least in regard to men, peaked in the early 1950s and

declined sizably even before the landmark *Report to the Surgeon General on Smoking and Health* in 1964. Thereafter the decline accelerated, particularly for adult men, so that by 1978 the proportion of men smoking cigarettes was at least 25 percent lower than in 1965 (Table V).[52,53] For both men and women, smoking has become a habit of a minority. Again, the higher the educational level, the more this is the case (Fig. 7).[52,53] These data clearly indicate that it is possible to impact the smoking situation, and that substantial progress has already been made. However, there are still big problems. Thus, the prevalence of heavy smoking—25 or more cigarettes per day—has apparently not yet decreased among adults.[52,53] And there is a big problem of smoking among teenagers, although data from the late 1970s indicate the beginnings of a decline.[54] And there is a special problem of millions of women who are smoking cigarettes and using the contraceptive pill.

Exercise: As you all know, one transformation—literally—in behavior in this country has been the large-scale adoption of leisure time exercise. Direct trend data on this are lacking as far as I know, although there are confirmatory data on sales of running shoes, tennis racquets, and so forth. Table VI gives the situation in 1977, and indicates that in this regard, as in all others, the change is more conspicuous among the more educated than among the less educated.[55] It is also greater among men than among women.

Control of high blood pressure: In the late 1960s and early 1970s, after publication of the landmark reports of the Veterans Administration antihypertensive drug trial,[56–58] it became increasingly a matter of concern that in the great majority of the millions with high blood pressure in our population the condition was undetected, untreated or uncontrolled.[59–61] This came to be known as the 1/2 by 1/2 by 1/2 phenomenon: about half the hypertensive population had their condition detected; about half of those whose condition was detected were being treated; and about half of those being treated had the condition controlled; that is, in only one in eight persons was the condition detected, treated and controlled. The Veterans Administration data on efficacy of treatment and the survey data on the low level of control were major foundations for the 1973 federal initiative establishing the National High Blood Pressure Education Program.[12] In the years since, the proportion

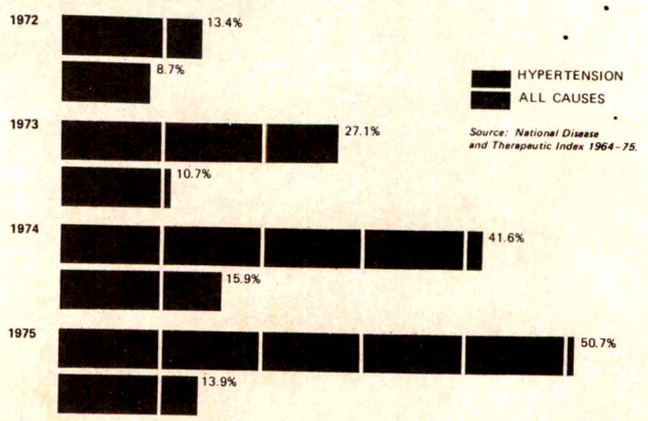

FIGURE 8. Patient visits for all causes and for hypertension and hypertensive heart disease (percent increase over 1971).

of hypertensive persons whose condition has been detected, treated and controlled has risen steadily. By the mid 1970s, it was approaching the 50 percent mark (Table VII).[60–63] However, I hasten to add that a substantial number of people with high blood pressure remain to be detected.

In agreement with the data on progress in the control effort, the number of patient visits to physicians—both first and repeated visits—for care for hypertensive disease has risen steadily, much more so than visits to physicians for all causes (Fig. 8).[63,64] A similar steady increase has occurred in the number of filled prescriptions for antihypertensive medication and the expenditure for such prescriptions (after correction for inflation).

The Possibilities for Prevention

Given these favorable trends among the American people in regard to the major coronary risk factors, how much of a decline in coronary mortality—and consequently in all causes of mortality, the bottom line—might be expected? A substantial decrease, based on extrapolation from prospective epidemiologic studies. Table VIII presents estimates based on the data of the national cooperative Pooling Project.[65,66] This is a conservative projection: a decrease in serum cholesterol of only 15 mg/dl, a decrease in mean diastolic pressure of the population of about 2 mm Hg due to improved control of hypertension, the reported decrease in percent of men smoking (Table V). The projected effect for white men of an average age of 50 is a 19 percent decrease in mortality due to coronary heart disease and a 13 percent decrease in mortality due to all causes.[67]

Data from two recently completed randomized controlled trials also give promising answers to this question: First, positive findings were reported from the primary prevention trial in Oslo, Norway, as presented last June to the European Congress of Cardiology in Paris.[68] The participants in this 5 year randomized controlled trial were nonhypertensive men aged 40 to 49 years, highly prone to the development of coronary artery disease because of hypercholesterolemia and cigarette smoking. Intervention with the experimental group involved nutritional recommendations to lower serum cholesterol, and—compared with the control men—the level was reduced 13 percent over the 5 years.

TABLE VII

Undetected, Untreated and Uncontrolled Hypertension, Chicago Heart Association (CHA) Detection Project in Industry (1967–1973), Hypertension Detection and Follow-Up Program (HDFP) (1973–1974), Community Hypertension Evaluation Clinic (CHEC) Program (1973–1975)

Diagnostic and Therapeutic Status at Screening	CHA (age 25–64 yr) (%)	HDFP (age 30–69 yr) (%)	CHEC (all ages) (%)
Not previously diagnosed, DBP ≥ 95 mm Hg	57	25	28
Previously diagnosed, not on treatment, DBP ≥ 95 mm Hg	18	21	11
Previously diagnosed, on treatment, DBP ≥ 95 mm Hg	13	16	17
Undetected, untreated or uncontrolled (sum of rows 1–3)	88	62	55
On treatment, controlled, DBP < 95 mm Hg	12	38	45
Hypertensive persons* (n)	6,089	36,304	220,217
Persons screened (n)	29,153	157,370	1,049,225

* Blood pressure at screening elevated, or positive history of diagnosed hypertension with current treatment and blood pressure at screening not elevated.
DBP = diastolic blood pressure.

Also, the men were advised to stop smoking; 31 percent did, compared with 19 percent of the control men. The 5 year incidence rate of coronary disease was reduced by 42 percent and the 5 year mortality rate due to coronary disease by almost 50 percent in the experimental compared with the control group.

Correspondingly, the Hypertension Detection and Follow-Up Program[69] recorded an overall reduction of more than 20 percent in mortality due to coronary and cardiovascular disease—and 17 percent in mortality due to all causes—in its Stepped Care group compared with its Referred Care group. A sizable proportion of the Referred Care group was treated; this was not a placebo-controlled trial. Therefore the significant result of this Program looms even larger in regard to the potential for prevention. As to its sizable stratum with entry diastolic pressures in the 90 to 104 range, and free of evidence of major target organ damage at entry, the most common type of hypertensive person in the population, almost 50 percent of all the hypertensive persons detected by the Program in its population screening, the result was even more dramatic: a reduction in all causes mortality of 28 percent—36 percent for the 90 to 94 substratum. These data, reported to the meeting of the College last March,[70] speak eloquently to the issue of ability to prolong life by the Hypertension Detection and Follow-Up Program Stepped Care regimen of vigorous sustained antihypertensive treatment to keep diastolic pressure below a normotensive goal.

The Decline in Mortality Due to Coronary Heart Disease

Well and good, then, as to the possibilities of prevention. What then has actually been happening "out there"? Figure 9 shows the course of coronary mortality

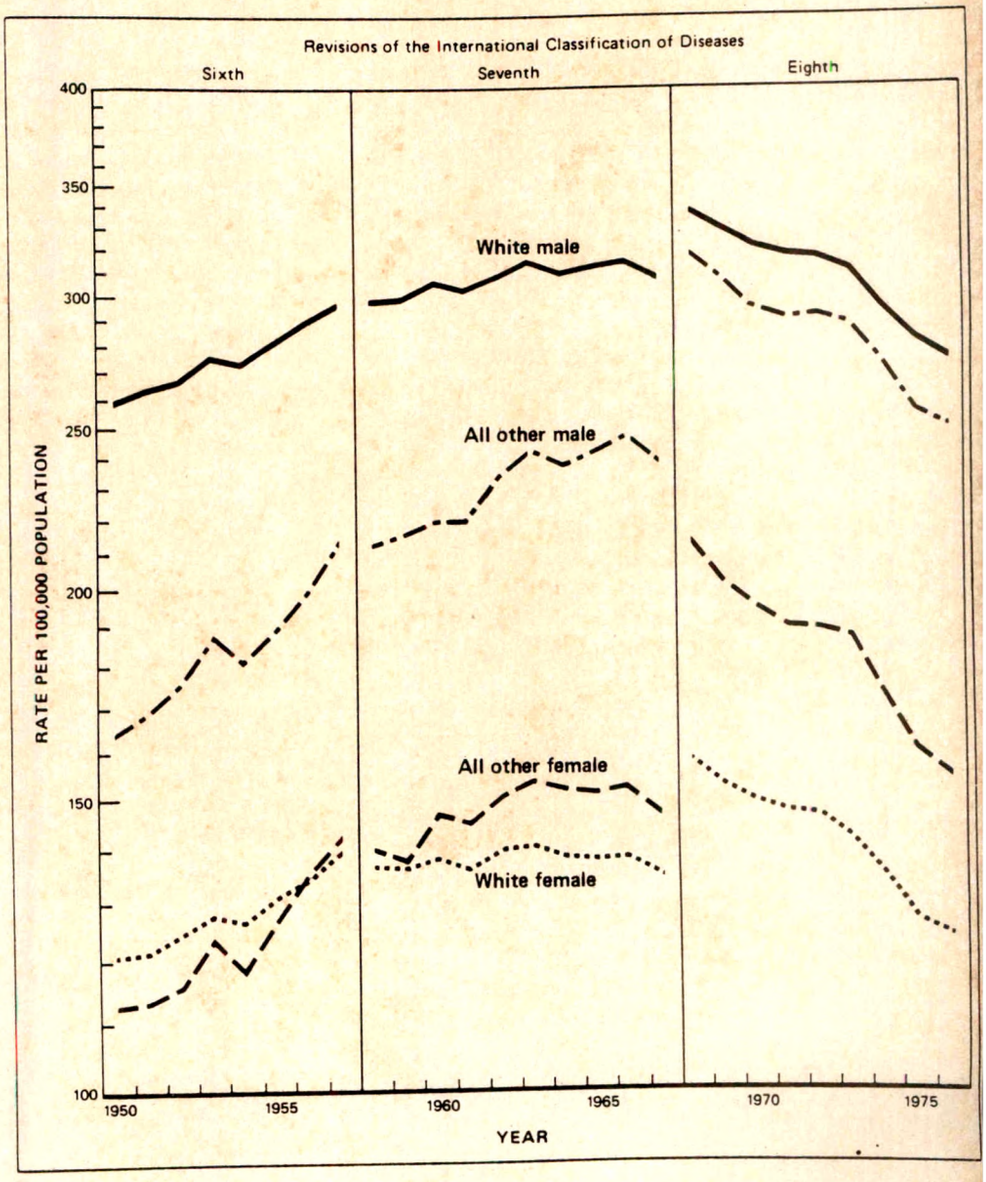

FIGURE 9. Age-adjusted death rates for ischemic heart disease, by color and sex (United States, 1950–1976), National Center for Health Statistics.

TABLE VIII

Expected Decrease in Coronary Heart Disease and All Causes of Mortality for Middle-Aged White American Men, Based on Reported Recent Changes in Population Risk Factor Status

Variable	Pooling Project (1950s)	Population Studies (mid 1970s)
Age (mean) (yr)	50	50
Serum cholesterol (mean) (mg/dl)	235	220*
Diastolic pressure (mean) (mm Hg)†	86.0	84.8
Cigarette smoking (%)	55%	40%
Expected 8.6 year mortality/1,000		
Coronary heart disease	50.4	41.7
All causes	120.4	105.7
Expected change in mortality/1,000		
Coronary heart disease	—	−17.3%
All causes	—	−12.2%

* % change −6.4 percent. † Percent of population hypertensive (diastolic blood pressure ≥95 mm Hg) in 1950s = 20 percent; percent of hypertensive persons detected, treated and controlled = 10 percent in 1950s, 50 percent in mid 1970s; mean diastolic blood pressure of persons with controlled hypertension = 90 mm Hg.

TABLE IX

Decline in Mortality Rate of Coronary Heart Disease, United States, 1968 to 1978 (persons aged 35–74, by sex and color)

Statistic	White Men	White Women	Non-White Men	Non-White Women	All
1968 rate	875.5	342.8	868.2	569.3	598.4
1978 rate	651.3	242.2	640.9	366.8	434.5
Difference	−224.2	−100.6	−227.3	−202.5	−163.9
% difference	−25.6%	−29.3%	−26.2%	−35.6%	−27.4%

Lives saved* 1969–78	317,743	170,119	39,596	40,592	568,050

* Based on expected deaths if the 1968 age-specific mortality rates had continued to prevail.
CHD—Coronary Heart Disease—ICD 410–413, 8th revision.
Rates, per 100,000 population, are averages of the rates for persons aged 35–44, 45–54, 55–64, 65–74.

in the United States since 1950—the steady rise, particularly for men, both white and black, that actually began in 1940 or even before—and then the dramatic break in the curve, the steady decline from 1968 on, continuing through 1978, the year of latest record.[71–73]

Table IX gives the details for persons aged 35 to 74 years, that is the age group being victimized by the epidemic of *premature* coronary heart disease: a decline of 26 percent for white and black men (in absolute units about 225 fewer deaths per 100,000 per year as of 1978) compared with 1968.[73] There are similar data for women. Overall, for all persons aged 35 to 74, there was a decrease of 27 percent, 164 fewer deaths per 100,000 per year. How many more persons aged 35 to 74 would have died in 1978 if the 1968 death rate had prevailed in that year? About 114,000—the lives that have been saved. And for the whole decade 1969 to 1978, a total of 568,000 lives have been saved.

Mortality rates due to stroke have declined even more dramatically (Table X).[73] And, given the decrease in coronary and stroke death rates, the "big two" among the major cardiovascular diseases, the death rate for that broad category has also fallen markedly, more so than for noncardiovascular diseases. The actual numbers merit attention: cardiovascular mortality down 28 percent, 235 per 100,000 fewer deaths in 1978 than 1968, about 164,000 premature cardiovascular deaths averted in 1978, and more than 800,000 lives saved from cardiovascular death over the decade 1969 to 1978—74 percent of all lives saved during those years. Despite the absolute increase in the population overall, and its middle-aged and aging segment, despite an increase of almost 2 years in the average age of our whole population, there was an absolute decline in all cardiovascular deaths, which peaked at 1,037,000 in 1973 and decreased to 962,000 in 1978 (Fig. 10).[73,74] *But,* these deaths are still too many—and still too many are occurring in the prime of life. *Our job is cut out for us.*

One study is available indicating that the decline in mortality may be part and parcel of a decline in incidence of acute myocardial infarction—as reflected by the trend of hospital admissions, in the Kaiser-Permanente system in northern California (Fig. 11).[75] Another data set—from New Orleans—indicates that in the 1970s, compared with almost a decade earlier, for both white and black men, severe atherosclerosis of the coronary arteries was less common at all ages from 25 to 44 (Fig. 12).[76]

A third study is in progress in Olmsted County, Minnesota; its results to date have been summarized by the investigator as follows: "I must repeat that we have not completed our comparability check, but it seems clear that there has been no change in the incidence of initial manifestation of [coronary heart disease] to parallel the decline in mortality."[77]

TABLE X

Decline in Mortality Rates, United States 1968 to 1978 (persons aged 35 to 74 years)

Statistic	Coronary Heart Disease	Cerebrovascular Diseases	Major Cardiovascular Diseases	All Causes
1968 rate	598.4	148.1	850.8	1,624.9
1978 rate	434.5	88.7	615.4	1,323.0
Difference	−163.9	−59.4	−235.4	−301.9
% difference	−27.4%	−40.1%	−27.7%	−18.6%
Lives saved* (1978)	113,908	40,248	163,520	216,206
Lives saved (1969–1978)	568,050	185,523	804,359	1,092,638

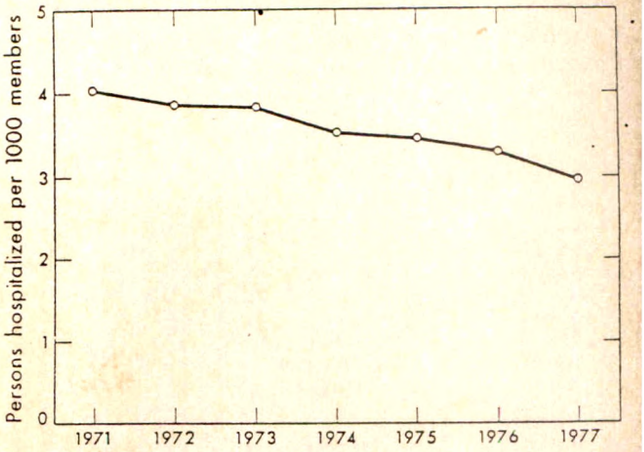

FIGURE 11. Age- and sex-adjusted proportions of subscribers, aged 35 to 84 years, hospitalized for acute myocardial infarction (International Classification of Diseases, adapted for the United States, code 410). Kaiser-Permanente Medical Care Program, northern California region, 1971–1977.

To the best of my knowledge, these are all the data so far available on U.S. trends of incidence of coronary heart disease and occurrence of severe atherosclerosis. We lack multiple data sets on these relevant trends—but two of the three cited pieces of information so far available are consistent with the massive data on the mortality trend.

In regard to decline in mortality, our country again has set the pace, as we have in the development of public policy and in beginning to improve life styles and control major risk factors. In 1968, our mortality rates due to coronary heart disease for middle-aged men were the highest in the English-speaking world. Thanks to the decline in mortality, by 1978 ours were the lowest, except for those of Canada—lower than the rates in Aus-

$$\frac{\text{QII–V Excess Events, 4,000 Men}}{\text{All Events, 5,000 Men}} = \frac{691.5}{1,105.0} = 62.6 \text{ percent, of all}$$

events are excess events, attributable to the three major risk factors.

tralia, England and Wales, Ireland, New Zealand, North Ireland, Scotland (Table XI)[78]; yet, I hasten to re-emphasize, still too high, still at epidemic levels. A large group of countries—in eastern, northern and western Europe—is still registering increases in mortality rates due to coronary heart disease—trends related statistically to national trends of dietary lipid intake and cigarette use.[67]

Implications of the data: On the basis of the Pooling Project data collected in the late 1950s and 1960s in Albany, Chicago, Framingham and Tecumseh, the estimate can readily be made that high levels of serum cholesterol, blood pressure and cigarette use were responsibile, conservatively, for about two thirds of all

TABLE XIII

Serum Cholesterol, Blood Pressure, Cigarette Use at Baseline—Quintiles of Risk of a First Major Coronary Event, Based on the Three Major Risk Factors, Multiple Logistic Analysis, 6,875 White Men Aged 40 to 59 Years, Pool 5, Pooling Project

Quintile	Mean Serum Cholesterol (mg/dl)	Mean Systolic Pressure (mm Hg)	Mean Diastolic Pressure (mm Hg)	Mean Cigarette Use, Packs/Day: Mean All	Mean Cigarette Smokers Only
I	206.0 ± 36.2*	124.7 ± 13.6	78.5 ± 8.1	0.36 ± 0.65	1.08 ± 0.71
II	221.9 ± 37.1	131.1 ± 15.1	83.1 ± 9.1	0.85 ± 0.93	1.48 ± 0.77
III	234.3 ± 41.0	134.6 ± 17.0	85.1 ± 9.7	1.20 ± 1.04	1.73 ± 0.81
IV	246.5 ± 43.3	138.8 ± 18.6	87.9 ± 10.5	1.63 ± 1.06	2.02 ± 0.79

major coronary events among the middle-aged American men in that set of cohorts. These are the excess cases, attributable to the major risk factors (Table XII).[65,66] The implications of these data are obvious: Our coronary rates would be lower by two thirds if all middle-aged American men had levels for these major risk factors like those of the lowest quintile (20 percent) of coronary risk in our population; that is, if our *overall* mean serum cholesterol level was about 205 mg/dl, not 235; if our *overall* mean blood pressure was about 120/80 mm Hg, not 136/86; if none, or almost none of us smoked cigarettes regularly (Table XIII).[66]

Over the last decade or so, we have been moving toward these more favorable goals, the more educated among us more so than the less educated—at least in regard to serum cholesterol and cigarette use. And in American men aged 35 to 74 years, the rates of coronary disease have declined by more than 25 percent. Moreover, data are available from the Metropolitan Life Insurance Company indicating that the decline is greater for the more educated than for the less educated.[79] This is of course the expected finding, given the greater degree of change in lifestyles and lifestyle-related risk factors in the more educated than in the less educated, if these changes are playing an important role in the mortality decline. That is, these data give further weight to the widely held estimate that the changes in life style and life style-related risk factors have made a key contribution to the decline in mortality due to coronary heart disease.

Given the trends over the last 10 years, I am prepared unabashedly to propose a goal: continue to work to reduce the still high death rate due to coronary heart disease by 3 percent a year over the decade of the 1980s, so that by 1990—compared with the peak in the late 1960s—the total decline is close to 60 percent, that is, close to the figure the Pooling Project data indicated as possible.

Conclusion

These data—together with all the other scientific evidence, and all the findings on what has happened over the last 20 years—are consistent with the conclusion that we have been on target in undertaking and developing the coronary prevention effort over the last 20 years. It is a reasonable inference, given all the facts, that the positive changes in lifestyles and risk factors among Americans relate causally to the decline so far registered in the coronary mortality rates. This is not only a reasonable inference from the facts, but also a reasonable conclusion based on fundamental theoretical grounds, that is, the basic generalization that epidemic disease is due to ". . . disturbances of human culture," to quote Virchow,[80] so that amelioration of these ". . . disturbances" induces abatement of the epidemic. Of course, it is very hard unequivocally to prove the validity of that inference. But in that regard, I call to your attention the sage remark of Darwin[81] on the shortcomings of excessive skepticism:

> I am not very skeptical,—a frame of mind which I believe to be injurious to the progress of science. A good deal of skepticism in a scientific man is advisable to avoid much loss of time, but I have met with not a few men, who, I feel sure, have often thus been deterred from experiment or observations which would have proved directly or indirectly serviceable.

My conclusion then is that there is good reason to keep on doing what we have begun to do—to do it more so and even better—and that is what this Conference is all about. Our purpose is humanism—longer life with better health—in the best Hippocratic traditions of medicine, in the spirit that Pasteur[11] put so well in these inspiring words:

> To him who devotes his life to science, nothing can give more happiness than increasing the number of discoveries, but his cup of joy is full when the results of his studies immediately find practical applications.

Changing Behavior for Health

DAVID A. HAMBURG, MD

On an occasion like this, we are concerned very much with the moving frontiers of science. We are not talking about freezing 1980 once and for all with respect to the prevention of coronary heart disease—let alone the behavioral component, which is, after all, a new field. The moving frontiers involve new information about risk factors and disease; there will be greater specificity in the future about what risk factors have what kind of relation to ultimate outcomes. I think there will be, particularly in the emerging area that some people call ecogenetics, better ways of specifying individuals at particularly high risk and therefore, among other things, of focusing behavioral interventions on people who are in greatest need of those interventions.

Behavioral Aspects of Health

In my mind, the decrease in cardiovascular mortality is one of the great stories of the modern era, as was the earlier prevention of rheumatic heart disease. I see much potential for further improvement in our capability to prevent cardiovascular disease, in light of scientific advances and their judicious application. Some of that has to do with the difficult general question: Can behavior change? We have some reasons to believe that in this sphere behavior can change, despite all the inherent difficulties of modifying gratifying patterns to which people are more or less addicted.

The National High Blood Pressure Education Program[1] is encouraging in that regard. The survey data on exercise, which can readily be confirmed by looking around us, are quite dramatic. Everybody is out jogging and playing tennis; you don't have to go very far to see that this is a behavior that has changed a good deal in recent years.

As for the role of physicians in changing behavior for health, I believe that role has been somewhat underestimated. And the key factor in it is the still enormous respect in the society at large for physicians and, in the world at large, for American medicine. That respect gives leverage that is virtually unparalleled for changing behavior in healthful directions.

We have in recent years seen a sea of change in medical and public awareness of the behavioral aspects of health and a tidal wave of new scientific developments in behavioral biology. These in turn are having a stimulating effect on a wider range of behavioral sciences. There is now certainly a broad awareness of behavioral factors pertaining to smoking, alcohol use and traumatic injuries—indeed, in relation to the etiology and pathogenesis of diseases and disabilities that constitute a large part of the burden of illness in this country.

We may have been a little slow to face up to aspects of these issues, but we are doing so now. In the Institute of Medicine, we have tried to respond to that heightened awareness of behavioral factors by seeking ways to strengthen the scientific capabilities that had, to a considerable extent, been neglected for a long time.

These problems are inherently interdisciplinary. Just a few weeks ago we published a report on scientific opportunities in alcohol problems,[2] a very exciting refutation of the conventional wisdom that there is no handle on the alcohol problem. The report deals with both biologic and social factors, as must be done in all major behavioral aspects of illness. Another study, on stress problems, will be out in a few months.

The third major study of the Institute will not be published until next year. Called "Health and Behavior, A Research Agenda," it is based on the six conferences of our Institute. Proceedings of the first conference, on smoking and behavior, have been published.[3] The second, still in preparation, was on the interaction of pharmacologic and psychosocial interventions, focusing on three major concerns, hypertension, diabetes and depression. Proceedings of the third conference, on biobehavior factors in sudden cardiac death will be published shortly. I need hardly say that the National Heart, Lung, and Blood Institute has had an important role in stimulating and fostering those studies.

The emergence of behavioral biology is an invigorating development in this field. It is not really my topic, although it has been a large part of my career. I just want to mention in passing that it seems to me that one of the crucial linkages in the biomedical and behavioral sciences occurs in a sort of final common pathway, namely, the brain's control, or at least strong regulatory influence, over the endocrine and autonomic nervous system.

When I was a student, we were taught that the endocrine and autonomic nervous systems were largely independent of central nervous system control. We now know how wrong that was. The great coordinating systems in the organism are two: the nervous system and the endocrine system. Work of recent years on hypothalamic hormones has shown specifically and tangibly the coordination of the coordinators, the neuroendocrine linkages, in directing the adjustments of the organism to changing conditions. But the research on hypothalamic hormones not only provided profound new insights of great intrinsic interest, but also a remarkable technology for peptide analysis.

Taken together, these advances, coinciding with the discovery of receptors in the brain and other related progress, have produced an explosion of neuropeptide discoveries in the past few years. I think that these discoveries have at least dimly foreseeable implications for our understanding and capacity to make useful in-

terventions over the next decade or two in various domains of health, disease and behavior. For example, there will be future implications for sexuality, alertness, pain relief, sense of well-being, relief of anxiety and depression, regulation of appetite, lowering of blood pressure, modification of learning and memory and a variety of cardiovascular and gastrointestinal effects.

I am not saying that the new pharmacology is here; I am saying that it is, to a certain extent, foreseeable and is likely to be much more specific than the old pharmacology, and has a very important potential in the current thrust of behavioral biology. In fact, an unprecedented array of molecular cell systems, techniques and concepts are now available for research on problems of behavioral medicine that would have been unimaginable 15 or 20 years ago. It is safe to predict a transforming effect on the field in perhaps another 15 or 20 years.

Social Learning and Cardiovascular Risk Factors

I shall devote the rest of my time to a discussion of learning and cardiovascular risk factors. It is, after all, the extraordinary human learning capacities that we are concerned with in talking about changing behavior for health. It would be surprising indeed if this most distinctive of all human characteristics, this learning capacity that so far outstrips that of any other species, could not be oriented toward what are in effect survival interests and concerns of the human species. It is true that the scientific approach to these questions is very recent, and most of the work has to be viewed as path-breaking and exploratory, but I call your attention to some promising and illuminating lines of inquiry that may have potential for future application.

Success in management of patients, let alone in prevention, depends in part on our understanding of human behavior. The scientific basis for our understanding of behavior and modifying it has been greatly strengthened in the past few decades by the emergence of authentic principles of learning based on experimental research in animals and human beings. Such analysis is concerned with identifying stimuli, especially rewards and punishments, that influence behavior. Understanding has increased with respect to stress and coping and with respect to the interaction of persons with their environment, particularly the social environment and the role of the social influences on behavior. The principles of learning have been utilized in recent years in new approaches to cardiovascular risk factors such as smoking and obesity.

Progress in research has demonstrated that behavioral intervention can be effective, but it is far from precise in terms of determining how effective it is for whom and under what conditions. A great deal of sorting out needs to go on. Such interventions are being tested not only in weight control and smoking cessation but also in promoting adherence to medical regimens. The emergence of a sizable cadre of behavioral investigators addressing problems like obesity is a very recent development, and the numbers are still far from satisfactory. The manpower need is great.

Obesity: Let me briefly summarize some prominent features of the work on obesity, a very tough area, but an important one. Much of the early work had important methodologic limitations. There is no question that behavioral strategies based on learning principles can be effective in achieving short-term weight loss. I emphasize short term. Patients in weight loss programs utilizing such strategies manifest a great deal of variability in their responses to treatment. Attempts to identify predictors of such variability have not been very successful. The magnitude of weight lost over the long term in most of the regimens has been marginal. With respect to clinical significance, evaluations of long-term maintenance are badly needed and, indeed, focus on continuing reinforcement for maintenence is a crucial direction in both clinical practice and research. Several trends are discernible in the newer crop of studies. One is a closer integration of behavioral and physiologic variables. Another is increased attention to physical activity, along with attention to eating behavior.

A wide range of psychological factors is being considered, especially those having to do with self-respect and alternative gratification. More rigorous experimental methods are being used as well as long-term follow-up and—points I want to emphasize—growing attention to the social factors that influence obesity and to prevention in childhood and adolescence. These latter trends are exemplified by the component on obesity in the Stanford Three Community Study.[4] This study relied heavily on principles of social learning, which I think is a very important concept. There was a component on dietary modification and reduction of obesity. The results suggest that significant dietary modification can be achieved through a large-scale community approach using both mass media and face to face intensive instruction components. This particular finding is now stimulating research efforts to influence persons through their home and work environments over their lifetime, rather than treating obese persons in isolation, which is a very discouraging enterprise. In planning community-wide educational programs, it is reasonable to focus on persons most likely to benefit from the best weight. That would mean moderately overweight adults, adolescents and children.

Smoking: With smoking, as with obesity, the task of interrupting a gratifying behavioral pattern on which the individual has become highly dependent is very difficult. We have to face it. It is harder than prevention by, say, cleaning up some foul-smelling sewers. But we have scarcely scratched the surface of what modern biobehavioral science might be able to do in this regard, since so few well trained investigators have addressed these problems.

There are three critical issues in smoking cessation research. One is improving intervention techniques and research methods, especially to prevent relapse. Another is providing the majority of smokers who want to quit with minimal outside aid. Another is focusing treatment on special groups of smokers, including pregnant women and women of child-bearing age, blue collar workers,

olunteers, persons who are medically at risk, and adlescent smokers. The workplace has come to be viewed s a promising site for intervention, with respect to both essation and prevention. I think that this area deserves nuch more vigorous pursuit now. Most adult smokers an be reached in the workplace.

Among men who smoke, the problem is heavily oncentrated among blue collar workers. They tend not o seek outside help, although surveys indicate their esire to stop smoking is similar to that of other smokrs. Working women smoke at a somewhat higher level han do women in the home. Workers in occupations nvolving asbestos, coal mining and cotton have a special levation of risk when they are smokers. The workplace rovides an environment for long-term social reinorcement. I emphasize the value of long-term social einforcement in maintaining nonsmoking behavior.

The critical problem for smoking cessation is naintenance of nonsmoking behavior over the long erm. Here again, lessons have been learned from the tanford heart disease prevention research.[4] Three ears after the program started, the proportion of mokers had decreased by 3 percent in the control ommunity, about 8 percent in the community in which moking education had been limited to use of the media nly and by 24 percent in the community receiving ersonal counseling as well as education through the nedia. Fifty percent of the high risk smokers receiving ace to face counseling had stopped smoking, compared vith 11 percent exposed to the media alone.

In the effort to obtain long-term smoking cessation, t is useful to compare the characteristics that distinuish abstainers and relapsers. The abstainers over the nger term tend to have a higher sense of efficacy as a erson, sense of worth as an individual and personal ommitment to the task; very importantly, they have nore social supports for smoking cessation, including nodels of coping provided by ex-smoker peers. These indings have implications for our preventive program. think we are moving away from a view of the individual ssentially in isolation in the short term to a view of the ndividual in a social context over the longer term and he role of the physician in facilitating the social suports to provide continuing reinforcement for healthmproving behavior. Here lies a great challenge to us ll.

The relapse rates in some studies have been reduced y buddy systems, peer support, interpersonal recogition for abstinence and the experience of helping thers to quit. That is an interesting point. In a number f spheres, the sense of having overcome some difficulty, t least for a while, and of being able to be useful to thers in overcoming the same difficulty is a very gratying one.

Finally, we are seeing increasingly the teaching of pecific coping responses, ways of handling particular tuations. This leads me to a more explicit considertion of the social factors, including influences of peers, arents and teachers, through instruction and example, eward and punishments. Some of these influences mpete with one another. For example, information about the dangers of cigarette smoking is in competition with observation of cigarette smoking in parents, teachers, and peers, that is, the attractive modeling of cigarette smoking. Also, the glamour depicted in advertising for cigarette smoking acts to overcome fears of its danger to health, so that the challenge of influencing cigarette smoking has brought about efforts to prevent children in early adolescence from becoming cigarette smokers. That seems to be a crucial area. Although adolescent smokers believe that cigarette smoking is unhealthy, this belief can be outweighed by peer pressure, models of smoking parents and attractive messages in models in the mass media.

Information is of value if it comes from a credible and respected source, but I think we have to go beyond the mere giving of information to training how to cope with social influences on smoking behavior. Training adolescents to resist social pressures is a focus of some interest now—specific instruction on ways to resist persuasive communications. Some programs are using videotapes to show adolescents in common social situations, focusing on short-term incentive such as kissing. How unattractive it is to kiss a smoker seems to carry more weight with a lot of adolescents than talking about what might happen 20 or 30 years downstream. These programs include a lot of practice in actual situations or simulated situations that involve resisting social pressure to smoke, a kind of inoculation against social pressure to smoke. The onset of adolescence is a critical period of biologic and psychosocial change. The adolescent years are highly formative for health-relevant behavioral patterns such as smoking, patterns of food intake, patterns of exercise, and so on. It is a period characterized by exploratory behavior. A lot of things are tried out, and some of the various patterns tried out become enduring patterns of behavior. Thus, health intervention programs in this period have a high potentiality for increasing the likelihood that the patterns will stick, will become enduring ones, consistent with the maintenance of good health.

But is has been historically difficult. We have not known very well how to communicate with adolescents, and these young people have fallen between the stools in health services, between pediatrics and medicine, between adult and child psychiatry. The potential of the school programs in health in the new era has yet to be fulfilled. One program involves peer counseling—that is, training peers to work together, providing continuing supervision.

Peer counseling approach: Instruction and content of peer counseling programs may differ. Some of the content in programs I have been connected with involves the tasks and strategies of that particular circumstance in which people find themselves in phases of the life cycle, setting ways of coping with the experiences that they find distressful, particularly aspects of human relation that are so crucial to all of our lives. There is certainly some indication that good peer counseling programs can be beneficial to both the counselors and counselees. Some studies over the past few years have taken this peer counseling approach,

which arose in other contexts, and applied it to the onset of tobacco dependency. There are field experiments, for example, in which 16 year olds communicate skills to 12 year olds—for example, resisting peer pressure—with hundreds of students in matched experimental and control schools. These groups have been compared on cigarette smoking rates at the start of the program with follow-up periods not exceeding 2 years.[5,6]

The results are encouraging to this point. There is much less smoking among the adolescents exposed to peer counseling programs than among the control groups. Of course, the advantage of peer counseling is the great credibility of peers, one adolescent talking to another, but adult guidance and, preferably, medical guidance are needed in these peer counseling programs.

Community-Based Studies and Programs

Let me come back for just a moment to the Stanford Heart Disease Prevention Program, because it was one of the path-breaking studies, and it had more behavioral science sophistication than many of the others and provided considerable insight into behavioral change. The key aspects of this field experiment were the following: (1) The design of the campaign was based on an analysis of the knowledge deficits and the media consumption patterns of the intended audience—that is, meeting the needs of the local people in a comprehensible way; (2) the mass media approaches and the face to face instruction were based on established principles and methods of behavioral science, especially those of social learning; (3) the mass media materials were devised to teach specific behavioral skills—for example, preparation of a palatable low fat diet as well as offering health-relevant information and motivating people to use that information for their own benefit.

There was a 30 percent reduction in overall cardiovascular disease risk, although there are no specific data on the health outcomes—myocardial infarcts, and so forth—but there was risk factor reduction. It is noteworthy that the intensive individual instruction of high risk persons added to the media effort provided an extra benefit. There are hints in that experiment that these effects are probably better sustained if community leaders and family members are involved, thus building a social support network that can provide continuing reinforcement for healthful behavior.

Other studies have pursued different aspects of this problem in a more differentiated way. For example, Blackburn's study has differentiated results of the effects of different media for different audiences.[7] The Pennsylvania study is going much more deeply into matters of community organization.[8]

The famous study in Finland, which does have data on some health outcomes as well as on risk factor reduction, involved a comprehensive community program, really comprehensive—using mass media, general health education measures, provision of practical services, training of local personnel, environmental changes, and installation of communication and information systems.[9] It elicited a remarkable degree of cooperation from both industry and government. And one has to say that the results of the project are encouraging. So many things were done that it is hard to single out one or two key factors in it, although my impression is that the results indicate the effectiveness of social networks in diffusing information, initiating behavioral change and maintaining reduction in cigarette smoking, serum cholesterol levels and blood pressure levels.

The potentially important Oslo study gives further encouragement in this regard.[10] It was effective in lowering two major risk factors in its participants, hypercholesterolemia and cigarette smoking, and it has data indicating a sizable reduction in coronary incidents and mortality. I would like to know more about behavioral interventions, since they seem to have been beneficial with respect to smoking and hyperlipidemia in healthy, normal middle-aged men. Particularly if it turns out that their health outcome measures are indeed positive, it will be important to learn in detail the nature of the behavioral interventions, which have not yet been published.

Components and tasks of community-based studies: In all of these community-based studies, which involve some mixture of broad public education and medical prevention, there are several tasks that deserve special attention. This is my reading of what at least are some of the factors that cut across the Stanford, Oslo, North Karelia and other studies in this field. (1) Providing specific, comprehensible information regarding the nature of the threat to health. (2) Providing specific, comprehensible information about the skills helpful in coping with the risk factors—what can you do. (3) Prompt reinforcement of early changes of behavior toward health-promoting patterns. (4) Community organization in ways that provide respected models in the community of health-promoting behavior and long-term social reinforcements for such behavior. (5) Involvement in health education of not just the individual alone but the family. (6) The formulation of educational messages in such ways as to link health-promoting behavior with self-respect—a key aspect of human experience—self-respect in the sense of personal worth and of course motivation fundamental to survival. (7) Utilization of school and work sites. (8) Utilization of specific media for specific audiences. For example, the radio is very significant for adolescents.

In practice, such interventions—I would say categorically—will profit in general from physician leadership, physician leadership in the spirit of collaboration with community organizations and the educational sector including the media. Overall, such programs have to be concerned not only with the general population but with specific sectors of the population like adolescents or the black community and then with the individual.

Role of Stress and Social Support Systems

I shall close with a word about another insight into social factors and a little bit more about human relations, especially the deep attachments among people that are such a crucial part of the human experience

altogether and seem increasingly to have relevance to various diseases. From various epidemiological studies of different designs in different countries, in different populations with different health outcome measures and stress indicators, there has been impressive convergence of evidence indicating that many disorders are precipitated by environmental stresses such as moving, unemployment and bereavement.

A recent report of unusual interest in this context is one from the Human Population Laboratory in California, looking at the ties between social linkages and mortality, Berkman and Symes' work[11]—a random sample of about 7,000 adults with a subsequent 9 month mortality follow-up. People who lacked social attachments were much more likely to die in the follow-up period than were those with extensive contacts. And, surprisingly to me at least, this finding seems to be independent of the known major risk factors.

Natural support systems can be effective in buffering stressful experiences. They also can influence the use of health services and adherence to medical regimens. This is pertinent to the requirements for behavioral change and prevention, smoking cessation, weight control or long-term adherence to antihypertensive medication.

It is also very important for the prevention of health-damaging behavior, because social support systems facilitate the development of coping strategies and help people contain emotional distress, maintain self-respect, preserve relations with other people, meet the requirements of new situations and prepare for the future. Thus an important opportunity in medical practice is to help patients mobilize latent support systems—for example, family, friends, community resource people. In so doing, we may become increasingly effective in changing behavior for health.

Task Force 1: The Physician and Children (Pediatric and Adolescent Practice and the School)

MARY JANE JESSE, MD, FACC, (CHAIRMAN), MATTHEW M. COHEN, MD, NICHOLAS CUNNINGHAM, MD, WALLACE G. FRASHER, Jr., MD, PETER HAUGHTON, MD, SUE Y. S. KIMM, MD, DOUGLAS R. KNAB, MD, CAPT, MC, USN, PAUL G. KOELLNER, MD, CAROL LURIE, HORACE G. OGDEN, SAMUEL O. SAPIN, MD, RICHARD M. SCHIEKEN, MD, FACC, JAMES A. SCHOENBERGER, MD, FACC, WILLIAM H. WEIDMAN, MD

I. Introduction

Physicians who take care of the child have long recognized and acted on two premises:

A. Events that occur from birth through adolescence may provide the template for the adult and his state of health.

B. Promotion of good health improves that template, and thus prevention of disease becomes a high priority in the care of children.

These physicians have learned over the past decade that there is now a role to play in the prevention of atherosclerosis and of coronary heart disease, the greatest killer of adults in the United States. The physician who takes care of the child has learned about the risk factors that are linked to heart disease in the adult. Investigation among childhood populations has indicated that habits set in childhood lead to the presence of risk factors in adult life. In some children, these risk factors are already present. *The major risk factors are:*

A. Elevated levels of serum total cholesterol and low density lipoprotein cholesterol.

B. Elevated blood pressure.

C. Cigarette smoking.

Prevention of the development of these risk factors in the child and intervention to control them where present hold promise for substantial improvement in the good cardiac health of the adult.

The physician who takes care of the child should encourage each individual patient and family to assume responsibility for protecting his or her and their own health. Health promotion is the process of fostering awareness, influencing attitudes and identifying alternatives so that an individual and family can make informed choices and change behavior to achieve an optimal level of physical and mental health and an improved physical and social environment.[1]

The physician promotes, through health education, the imparting of factual information, but additionally makes planned attempts to improve health-related behavior.[2] There are many ways the physician can educate patients and their families. For maximal effect, methods should stimulate the individual patient's involvement in health maintenance rather than just attempt to convey knowledge. Transfer of knowledge by itself does not necessarily result in better health and improved quality of life.[3,4]

The purpose of this report is to guide physicians who take care of children as to what is known, how they may play a role in influencing the risk factors that may threaten cardiovascular health in adulthood, and where and by whom such preventive efforts should be pursued.

II. Current Knowledge

A. Risk Factors

1. Elevated serum cholesterol levels: Mean serum cholesterol levels of 100 to 150 mg/dl are found in children in most areas of the world where there is a small incidence of coronary artery disease in adults. These compare with mean levels of 150 to 200 mg/dl in the youth from populations where there is a large incidence of coronary artery disease in adults.

Mean levels of total cholesterol of 150 to 180 mg/dl in adults in the population are consistently related to the lowest rates of coronary artery disease, and average cholesterol levels of 120 to 160 mg/dl for children may be necessary to achieve these optimal adult levels.[5] Differences in diet appear in part to be responsible for population differences in serum cholesterol levels.[6]

The level of serum cholesterol in an individual is affected by several interrelated factors, including genetic differences in metabolic pathways[7] and in responses to cholesterol and saturated fat in the diet.[8,9] In children in whom a cholesterol metabolic pathway abnormality is a strong factor, it may not be possible to lower the serum cholesterol to the desired level with diet alone. There are individual differences in the strengths of these two factors, and these affect the response of serum cholesterol to restriction of cholesterol and saturated fat in the diet.

Distributions of lipid-lipoprotein levels in the childhood population are now available.[10] A child's lipid level may now be followed sequentially according

to percentiles for age. Routine and community mass screening of serum lipid levels in children is not recommended. However, children from families with a history of premature myocardial infarction (before age 60 years) have an increased risk of having hyperlipidemia and should be screened.[7,11,12] Children of families with known hyperlipidemia or a strong family history of hypertension, or both, should also be studied.

Cholesterol is distributed among the lipoprotein fractions, most being carried by low (LDL) and high (HDL) density lipoproteins. Risk of coronary artery disease in the adult is probably related particularly to the low density lipoprotein level. Population studies suggest that high density lipoprotein levels have a protective effect in regard to development of atherosclerosis.[13,14]

If a child from a high risk family has two elevated serum total cholesterol measurements, lipoprotein fractions should be measured to determine the distribution of total cholesterol among the lipid fractions. This information may be useful as more is learned about factors affecting cholesterol distribution among the lipoprotein fractions. However, it is premature to give prognostic significance to elevated HDL cholesterol levels in children; for the present, attention should be directed toward total serum cholesterol level and LDL cholesterol.

2. Elevated blood pressure: The definition of hypertension in a child or adolescent is understandably arbitrary. All would agree that definite hypertension is present if the criteria of the World Health Organization are fulfilled, that is, systolic or diastolic pressure, or both, is repeatedly 160/95 mm Hg or higher. Hypertension at this level in preadolescence carries at least as great a health hazard as it does in adulthood, and every effort should be made to find any known cause. Interest is now being focused on children and adolescents who have average blood pressure measurements in the higher distribution deciles for age and sex, borderline hypertension or high normal levels.

A recent study has shown that American white men aged 40 to 59 years with a diastolic blood pressure between 80 and 88 mm Hg have a 42 percent greater risk of coronary artery disease than do those with a diastolic pressure equal to or less than 80 mm Hg.[12] Another study[15] of adults who as teenage boys had a systolic blood pressure equal to or greater than 130 mm Hg showed an increased risk of coronary artery disease in later years compared with those whose systolic pressure had been less than 130 mm Hg.[15]

Borderline hypertension has been defined as systolic or diastolic pressure, or both, at or above the 95th percentile of the distribution for age and sex on three repeated measurements, and absence of a secondary cause.[16] An alternate definition is the World Health Organization definition of adult borderline hypertension: blood pressure of 140 to 159 mm Hg systolic or 90 to 94 mm Hg diastolic.

Epidemiologic data suggest that at least some children with transient "spikes" of blood pressure into the hypertensive range continue to have blood pressures at this level through pre-adult and adult years.[17–19] However, not all children and adolescents with such "spikes" will later have sustained hypertension. One longitudinal study[20] of young adults with this phenomenon revealed that on follow-up study almost 80 percent were normotensive, about 10 percent had continued "spiking" and another 10 percent had sustained hypertension. The Muscatine, Iowa study[21] showed that of children who had elevated blood pressure at or above the 95th percentile on a single measurement, fewer than 1 percent were found to have persistent blood pressure elevations on repeated examination and more than half of these were obese. It is not possible at present to predict which children and adolescents with blood pressure "spikes" are at risk of having sustained hypertension. However, those children who are obese or who have hemodynamic manifestations of increased cardiac output (increased heart rate or systolic murmurs, or both) or who have one or more hypertensive parents are likely to carry a high risk of having sustained hypertension.[22,23]

3. Cigarette smoking: Cigarette smoking is one of the major risk factors for accelerated atherosclerosis and a major environmental cause of cancer and chronic obstructive lung disease. In addition, for the unborn, cigarette smoking by the mother has been shown to affect birth weight adversely. Cigarette smoking prevalence figures are estimates, because the data are based on varying definitions and self-reporting. Nevertheless, it appears that among adults, the proportion of men smoking cigarettes in the late 1970s was substantially less than that in 1964, whereas for women the reduction has been slight among whites and has not been seen at all among blacks.[24] It is clear that the habit begins early in life (ages 12 to 14) in substantial numbers and reaches epidemic proportions for teenagers aged 17 to 18 years. Again, a sizable downward trend for boys has been reported since 1970; for girls there was a steady rise in prevalence up to the mid 1970s, but a decline for all but the 17 and 18 year olds by 1979.[25–27] Thus the data indicate the possibility of progress in this area.

The reasons why American adolescents and teenagers smoke cigarettes have been studied intensively. It is known that when both parents or an older sibling smokes the child is much more likely to smoke. Success in academic studies and educational achievement are inversely related to smoking. Peer pressure has usually been cited as a major reason for smoking. The role of ubiquitous and persuasive advertising in the mass media cannot be assessed as an isolated influence but it has undoubtedly been a major factor in the decision to smoke.

The paradox in such widespread smoking by youth is the finding that the vast majority are aware of the dangers to health from smoking. Continued smoking under these circumstances suggests that conformity with group norms far outweighs fear of personal harm. Added to this are the risk-taking and defiance of adult standards so characteristic of some youth. Because it is apparent that many people smoke without immediate ill effect, the known dangers associated with smoking are not considered personally relevant to those adolescents and teenagers who start to smoke. There appears

to be a widespread delusion that youthful smokers have less difficulty quitting the habit.

B.. Risk Indicators

1. Obesity: Obesity has not been shown to be an independent health hazard in children; however, obesity is closely associated with hypertension, hyperlipidemia and diabetes mellitus in the adult. Overweight teenage college entrants are at greater risk of dying of coronary heart disease in middle age.[15] The obese child is at greater risk of becoming an obese adult, and thereby has a greater risk of having cardiovascular disease or diabetes mellitus, or both. Recent studies have shown a correlation between body mass and blood pressure in children and adolescents.[28–30] Many of these children and adolescents were obese. In addition, data from the Muscatine, Iowa study[21] and other investigations indicated that obesity plays a role in those children who have borderline hypertension on repeated measurement. Because of the association of obesity with hypertension, weight control is an important preventive measure in children. Finally, a recent conference held by the Nutrition Committee of the American Academy of Pediatrics concluded that obesity in a child had a profound psychosocial effect and recommended that preventive measures would have a beneficial effect.

The term *obesity* refers to an increase in body fat. *Overweight* refers to excess in body weight relative to standards for height. For most situations, overweight and obesity are used synonymously, although they are not identical. The clear definition of obesity is difficult because of the problems involved in measuring the contribution of fat to total body weight. Skinfold thickness has been used extensively to estimate the degree of obesity, but its value has not been adequately assessed through a wide range of obesity.[31] Until a practical method to measure total body fat is developed, a reasonable definition of obesity in a child is a relative weight (ratio of actual weight to expected weight for age, sex and height) of 120 percent or more plus a triceps skinfold thickness at or above the 90th percentile, or, in absence of skinfold measurement, visual assessment of the child as obese.

2. Physical inactivity: Physical inactivity is a risk indicator in children. The chance of obesity is increased and the sedentary habit may persist into adult years. There is no clear-cut evidence that exercise exerts an independent effect on prevention of coronary disease. However, regular exercise is to some degree associated with lean body mass and with a high level of HDL cholesterol. Also, although data are lacking, regular exercise may reduce tension and stress.

Perhaps most importantly, regular exercise promotes the concept of respect for one's body and reinforces efforts to eat a healthy diet, avoid the smoking habit, maintain physical fitness and avoid obesity.

III. Preventive Actions

A program directed toward preventing or retarding atherosclerosis, and risk factors for adult coronary heart disease and stroke, should include the following:

Identification and management of children with elevated serum lipids (Table I).

Identification and management of children with borderline and definite hypertension (Table II).

Identification and management of children with obesity (Table III).

Prevention of smoking.

TABLE I

Serum Cholesterol

Categorization	Action
Children with a family history of disease: 1. Hyperlipidemia 2. Premature cardiovascular disease 3. Hypertension	1. Measure total cholesterol × 3. If average at or above 95th percentile, measure lipoprotein fractions. 2. Measure total cholesterol in parents and their children. 3. Measure blood pressure in all. 4. Restrict saturated fat and cholesterol in diet. A. ≤300 mg cholesterol/day. B. 35% of total calories from fat/day. (1) 10% total calories: saturated fats. (2) *No more* than 10% calories: polyunsaturated fats. (3) Remainder monosaturated fats. 5. Discontinue oral contraceptives. 6. Reduce caloric intake if obesity present. 7. If no response to diet, refer for further evaluation.
Healthy children	1. Measure cholesterol levels only in those from high risk families. 2. Measure blood pressure levels annually and control obesity. 3. Healthy diet as above.

TABLE II

Blood Pressure

Criteria	Action
Definite hypertension (160/95 mm Hg × 3)	1. Staged medical evaluation. 2. Rule out secondary hypertension.[16]
Borderline hypertension (95th percentile or 140/90 ≤ 160/95 mm Hg × 3)	If still borderline: 1. Urinalysis and blood urea nitrogen determination. 2. Treat or prevent obesity. 3. Limit salt. 4. Discontinue alcohol. 5. Increase physical activity. 6. Discontinue oral contraceptives. 7. Continue evaluation and management.

TABLE III

Obesity

Criteria	Action
1. Greater than 120% of expected weight for height and age + 2. Skinfold thickness greater than the 90th percentile or visual estimate of obesity	1. Restrict calories to prevent excessive increase in body weight during growth period. 2. Restrict calories to reduce weight to normal after cessation of skeletal growth. 3. Develop habits to increase physical activity.

Development of the desire and habit to maintain a physically active life that will carry into adult years.

Development early in life of eating habits in the entire population that will promote a diet with adequate, but not excessive total calories, fat, cholesterol and salt.

The physician serving as a role model for good heart health habits for the child.

The physician serving as an advocate for health in the community.

A. Diet

Two of the major risk factors, hypercholesterolemia and hypertension, involve dietary intake. Until recently the main nutritional concern has been the issue of dietary adequacy. From the past emphasis on "adequate" or "balanced" diets there has been a shift to "prudent," "recommended" or "desirable" diets. It is no longer deemed appropriate to urge the public to eat more meat, dairy products, eggs, fruits, vegetables and cereal grains to obtain enough proteins, vitamins and minerals. There is new awareness that current mortality and morbidity in the United States are linked to a great extent to our dietary practices of *overconsumption* of specific foodstuffs. Thus, we are now concerned with the issue of maximal allowable (or desirable) levels of dietary intake as well as with minimal requirements.

Three dietary factors are currently known to be involved in coronary artery disease: These are (1) excessive intake of calories; (2) excessive intake of salt; and (3) excessive intake of saturated fats and cholesterol. The latter two factors often stem from the first. As a result, achieving proper caloric intake for an individual can begin to diminish excessive intake of saturated fats and cholesterol, and to lower intake of salt.

There are several approaches to estimating the optimal intake of calories for preventing obesity. The first approach is to rely on the current Recommended Daily Dietary Allowance standards (1980 revision).[32] These are:

Ages (yr)	Calories (kcal)
Boys and Girls	
1–3	1,300
4–6	1,700
7–10	2,400
Boys	
11–14	2,700
15–18	2,800
Girls	
11–14	2,200
15–18	2,100

Energy allowances for children (through age 18) are based on median energy intakes of children of these ages who were followed in longitudinal growth studies.[33]

Another approach is to propose that caloric recommendations for normal childhood populations should be related to the mean caloric intake of the different age groups:[33]

Mean Caloric Intakes (with standard deviations) by Age and Sex Groups

Age (yr)	Calories (kcal) Boys	Girls
1	1,332 ± 452	1,220 ± 406
2–3	1,555 ± 568	1,429 ± 555
4–5	1,851 ± 627	1,617 ± 524
6–7	2,082 ± 601	1,847 ± 619
8–9	2,222 ± 705	1,893 ± 601
10–11	2,317 ± 720	2,051 ± 771
12–14	2,607 ± 922	1,915 ± 699
15–17	3,097 ± 1,221	1,761 ± 699

These values are the mean caloric intake of white children in homes where income is above poverty level because black children and low income groups in the United States are leaner and, therefore, possibly undernourished.

These standards take into account neither amount of activity nor weight status (that is, whether under-or overweight). Thus, the standard may include too many calories for those who are relatively inactive and overweight and too few perhaps for those who are extremely active and underweight. Nevertheless, it is helpful to have guidelines for general recommendations of caloric needs of the different childhood age groups.

B. Dietary Fats and Cholesterol

As a guide, a diet for healthy children beyond infancy containing no more than 300 mg/day of cholesterol with 35 percent of the total calories derived from fat, less than 10 percent from saturated fat, about 15 percent from monounsaturated fat, and *no more than* 10 percent from polyunsaturated fat is safe and can be expected to result in lower serum cholesterol levels. To decrease dietary cholesterol intake as well as saturated fats, the child should eat less fatty meats, fat-containing dairy products and egg yolks. Healthy children with a serum cholesterol level of less than 160 mg/dl are unlikely to have a significant decrease in level when eating a low cholesterol, low saturated fat diet.[9]

It is important to remember that there are some childhood populations in the United States whose diet is not adequate in energy content and they may be inappropriately advised to follow such a nutritional practice.

Children with a family history of hyperlipidemia or premature cardiovascular disease have an increased risk of having hyperlipidemia.[7,11] Whether treatment for hyperlipidemia, other than diet, is indicated must be assessed individually. This depends in part on level of total serum cholesterol before dietary intervention and extent of response of serum cholesterol levels to the low cholesterol, low saturated fat diet. Use of the contraceptive pill is to be avoided when hyperlipidemia is present or when it develops with use of the pill.

C. Hypertension

As indicated, the prevention and correction of obesity in childhood and youth appear to have a great potential for reducing the level of blood pressure.

Numerous epidemiologic and animal model studies have shown that excessive dietary sodium is associated with an increased risk of hypertension, particularly for those with a genetic predisposition.[34,35] A reasonable recommendation is to limit the intake of salt to no more than 5 g (86 mEq sodium)/day. A diet of 5 g of salt/day could be achieved by eliminating most highly salted processed foods and sodium-containing condiments and by eliminating added salt at the table.

Given the several recent reports on the association between heavy intake of alcohol and high blood pressure, physicians have an added reason to do everything possible to prevent and correct the patterns of excessive alcohol use now all too common among youth.[36–39]

All children over the age of 3 years should have their blood pressure measured annually. In communities with children who are not seen regularly in a health care facility, physicians should assist in developing a system in which blood pressure measurement can be carried out. This is especially important in communities of black children, who are at particularly high risk of hypertension as adults.

D. Cigarette Smoking

Physicians and health care planners must build on positive motivations for achieving and maintaining optimal health. The role of the individual in accepting primary responsibility for his or her own good health must be one important basis for any anti-smoking program directed at youth. The physician must play a key role in supporting such an effort.

1. *Smoking in the doctor's office should be forbidden to all.*

2. *The physician should advise all patients beginning at an early age (perhaps 5 or 6 years) and repeated at each contact not to smoke.* This advice should be based primarily on positive aspects of maintaining optimal health rather than arousal of fear.

3. *Smoking habits of each patient should be elicited by the physician.* The physician should make every effort to persuade a child who smokes to stop.

4. *The physician should provide educational material related to smoking cessation.* Materials are available from the local American Heart Association, the local Lung Association, the National Cancer Institute (National Institutes of Health, Bethesda, Maryland 20205).

5. *The physician should refer smokers to cessation programs* and play an active role in the development of such resources.

6. *The physician must regularly monitor smoking habits of his patients,* taking advantage of recurrent desire on the part of recidivists to try again to quit. Unrelenting persuasion using all available techniques should be employed. The physician should never adopt a punitive, judgmental or defeatist attitude.

7. *For inner city unemployed youth,* the problem of drug abuse including cigarette smoking may not be dealt with successfully until underlying social problems are solved.

E. Exercise

Establishing the habit of regular exercise in childhood is appropriate and can lead to continuation of that good habit in adult life. Physicians and their families can serve as role models for the child and his family by engaging in regular exercise activity. They should include in a history a series of questions about exercise, including whether the child has entered the Presidential Award Program.

The physician should encourage exercise that the child will enjoy and is likely to continue through life, such as walking, climbing, social dancing, tennis, jogging, swimming, bicycling and cross-country skiing. Thus, the emphasis should be more on fun than on victory or record setting. Exercise is an important adjunct in the prevention and management of obesity.

F. Promoting Healthy Habits

The effective communication of health-related information from a busy physician to pediatric and adolescent patients and their families is one important aspect of the process of prevention of cardiovascular disease. This requires familiarity with basic educational techniques and a specific plan tailored to the particular needs of patients enrolled in a practice.[40–42]

The primary focus should be on those patients already motivated to acquire health-related information. The most challenging educational task is probably that of persuading the reluctant patient or family to seek information and help. Good listening and an enthusiastic approach at the outset of providing medical care can motivate even indolent, irresolute and hostile patients.

A variety of materials are available. The patient information booklet is the most common orientation method used by the physician.[42–45] The booklet should be targeted to the practice population's specific health beliefs and needs and should openly promote patient-doctor dialog. The physician's enthusiastic and brief oral overview of the booklet encourages its use and enhances the value of its content.

The most common method of patient education is one-to-one discussion. Although the use of this method best promotes the patient-doctor relation, it is better for reasons of time, energy and effectiveness to use an "educational prescription"—a mixture of educational modalities. This is particularly important for the patient being treated for a health hazard or risk factor, and should include written material to be read and taken home for others in the family to read, as well as referrals to appropriate agencies and programs.

Written materials are widely available, easy to distribute, economical, easy to update and can be distributed according to a tailor-made preventive care protocol. Thus, the obstetrician or family practice physician might establish a protocol to discuss family diet, smoking, and exercise habits, and to offer parenting advice, at a time when the prospective parents are most impressionable.

A variety of other methods can be used in the office: bulletin boards, posters, audiovisual programs, or even

patient libraries, depending on the characteristics of the practice.

Inherent in an effective educational program is good record-keeping to record the patient's progress within the suggested health maintenance education program or to assess compliance with a high risk protocol. Patient involvement is also enhanced by keeping a health maintenance record. The length of a patient's visit need not be extended. The repetitive nature of visits by children to their physicians allows constant reinforcement of good cardiovascular health habits.

The focus for preventive programs in Health Maintenance Organizations (HMO) remains to be sharpened. Physicians who work in such settings have a real opportunity to set up Cardiovascular Health Maintenance programs for the whole family. Implicit in the name HMO is the concept of preserving health, rather than sickness care. The promotion of preventive medicine makes good economic sense for society as a whole, but it is especially desirable in an HMO. Because the HMO utilizes the prepayment mechanism to finance medical care services, keeping the HMO member well will theoretically at least result in less utilization of resources and be financially advantageous to both providers and members.

3. School and Community Programs

It is important for physicians to be aware of the need to stimulate the development of health education programs outside their offices. These programs are aimed at the development and maintenance of good health habits and should be in place in the community school and college systems. Teaching large groups of children and young adults specific health education material pertaining to the acquisition and practice of optimal health habits should ideally take place through the curriculum in a sequential fashion from early grades through introductory college courses.

Because diet modification represents another major target of preventive intervention measures, physicians working in school and university medical care services should take every opportunity to help food services in these locations develop menus offering prudent diets and to educate students about them.

Physicians who work in school and university medical care services have access to students aged 17 through 21 years for whom risk assessment should be made and intervention initiated when appropriate. Their programs should provide blood pressure measurements for all students. They should identify adolescents and young adults with a family history of early death from cardiovascular disease, have serum cholesterol and lipoprotein determinations made, and do the same for young women in this group who are users of oral contraceptives.

Professional organizations whose cause is directed toward cardiovascular health have provided large amounts of educational material available to physicians and lay persons alike. The Americal Heart Association through its local chapters, the American College of Cardiology through its continuing medical education programs for physicians, the American Academy of Pediatrics through its Nutrition Committee and its newly formed Committee on Preventive Cardiology all serve as resources for the physician, the school and the community.

State governments are just beginning to approach the development of programs in prevention. The physician who plays a role in his own community's affairs should be in the forefront of support of programs that include cardiovascular health maintenance for children.

Finally, the physician who cares for children should let his Congressional representatives know of his support for the program in preventive cardiology mounted by the National Heart, Lung, and Blood Institute, which addresses in particular the training of physicians in Preventive Cardiology.

As the saying goes, "The child is father of the man." The child requires an advocate who aids him in the development of habits to maintain health, advocates wise programs to help in that mission and champions financial support for such programs.

Task Force 2: The Physician in the Office (Adult Medicine)

T. JOSEPH REEVES, MD, FACC (CHAIRMAN), ROSS BLACK, MD,
JOHN F. BURNUM, MD, SIMON DACK, MD, FACC, ROBERT B. EDMISTON, MD,
MARILYN FARRAND, GERALD R. GEHRINGER, MD, DAVID P. LAULER, MD,
HENRY D. McINTOSH, MD, FACC, JORGE C. RIOS, MD,
WERNER E. SAMSON, MD, FACC, CYNTHIA SCALZI, RN,
JEREMIAH STAMLER, MD, FACC, NANETTE K. WENGER, MD, FACC

I. Basic Assumptions

The recommendations of this Task Force are based upon the following fundamental tenets:

A. The current extreme prevalence of patients with significant coronary heart disease and annual incidence of acute coronary events continue to constitute our major public health problem.

B. The cost of coronary disease in premature death (often sudden and unexpected), disability (acute and chronic), and in financial aspects (loss of earnings and cost of medical care) is enormous. The annual cost has been estimated to exceed $30 billion in the United States alone.

C. Current American medical practice devotes a disproportionate effort toward the treatment of disease once symptomatic, as compared with that expended toward its prevention. But this treatment effort is often too late, for many deaths are sudden and unexpected;

and once a major heart attack has occurred, the loss of cardiac tissue is irrevocable and impairs function even if death does not rapidly ensue.

D. Evidence indicates that major reductions in the rate of development of atherosclerosis and of the incidence and prevalence of its associated diseases—coronary heart disease, stroke and peripheral vascular disease—can be effected if major "risk factors" relating to its pathogenesis can be appropriately controlled or modified. The modifiable or controllable risk factors most urgently requiring intervention include: (1) smoking of cigarettes; (2) hypertension: at all stages and all levels; and (3) hyperlipidemia, especially hypercholesterolemia. Other related factors amenable to change include life style traits such as physical inactivity, obesity and heavy alcohol consumption. Moreover, the association between coronary heart disease and certain personality characteristics ("type A personality") appears to be sufficiently great to justify more careful monitoring of such persons with these traits.

E. Risk factor control and prevention of coronary heart disease are matters of major concern for government at all levels, as well as major medical, professional and voluntary health agencies.

F. Physicians in community practice have an enormous potential for further progress in solving this national problem. Many physicians have already become engaged in prevention and this trend may be one of the contributing factors in the decline of coronary mortality in the past decade. However, physicians can and should be motivated into more effective action for this potential to be fully realized for the welfare of the citizens of this country.

G. Major additional efforts should be made by the practicing physician, in coordination with other community resources and with the responsible participation of the individual patient, to control risk factors for atherosclerosis and coronary disease.

II. General Strategy

Two major problems relate to effective utilization of practicing physicians as an efficient force for the prevention of atherosclerosis. The first is the task of enlisting them into a significant expansion of their current efforts toward this still underdeveloped part of the practice of medicine. The second relates to the specifics of the physician's efforts, both in his office and in a community-wide campaign. The most important problem is obtaining the enthusiastic support of the physician for this undertaking. If physicians become convinced that effective prevention of atherosclerosis and coronary heart disease could be materially enhanced through their efforts aimed at optimal control of major risk factors, these resourceful and able practitioners could develop or seek out more efficient methods for the accomplishment of this goal.

It is more logical and efficient, however, for the methodology to be developed simultaneously so as to be immediately at hand when the physician becomes convinced of the need for such systems. This conversion of the potential energy of the physician into a highly efficient force for changing the destructive life style of Americans at high risk will require a major concerted national effort. At present, there is no general consensus among practicing physicians as to what should be taught to their patients and their communities, or how additional information can be utilized by the physician to control risk factors in the practice setting and community. Beginning this important definition is a fundamental goal of this Task Force.

III. The Enlistment of the Physician to a Commitment to a Program to Prevent Atherosclerosis and Coronary Heart Disease

A successful utilization of physicians in the attack upon the major risk factors for atherosclerosis requires that they be convinced of the effectiveness and feasibility of their more vigorous participation in this preventive effort. The most influential medical organizations and their leaders will be required to transmit to the individual physician the significance of the available data regarding risk factor control and the prevention of coronary disease; the inevitable conclusion must be that adequate care of their patients and families demands more effective control of these major risk factors. These efforts at physician education should be coordinated through all of the appropriate health professional organizations at their national and local levels. Federal health agencies should be actively involved in planning and implementation of these programs.

Coordinating Steering Committees: If such massive effort is to be successful, strong and adequately funded leadership must be provided. It is logical for the leadership of the American College of Cardiology and the American Heart Association to coordinate the development of a Steering Committee comprising representatives of appropriate health professional organizations and federal health agencies to implement the recommendations of this Bethesda Conference. This Steering Committee could develop a mechanism to seek financial support from private foundations and from the National Institutes of Health and other government agencies. Funding of this effort may well be obtained from multiple sources. The magnitude of the problem clearly warrants such an effort. This Task Force believes the challenge and opportunity offered by this project is worthy of an intense effort of the concerned voluntary and governmental national agencies.

The details of the organizational effort required to mobilize the physicians of this country are beyond the scope of this Task Force report; however, one attractive possibility envisions utilization of the state organizations of the most concerned professional organizations as a focal point for leadership in each state. A Steering Committee for each state appointed by the National Steering Committee could be responsible for establishing a comprehensive educational program involving each county of that state; Fellows of the American College of Cardiology and Fellows of the Council of Clinical Cardiology of the American Heart Association, among others, could provide expertise in program presentation. "Kick-off" meetings of all major county

medical societies could be carried out almost simultaneously. Major local media coverage should be actively sought, with interviews and telecasts coordinated by the Steering Committee in conjunction with the local affiliate staff of the American Heart Association. Audiovisual materials, including slides and videotapes with a carefully documented text, could be made available for scientific programs. Materials preparation should be the responsibility of the Steering Committee, possibly in conjunction with the Department of Health and Human Services or other governmental agencies. The initial meetings should be followed by programs throughout the year, with presentations to staff meetings of each major hospital.

IV. What the Physician Should Do

A. Risk factor screening and care: Physicians are motivated to do those things that they perceive to result in good health care. Simple risk factor screening is in the realm of almost all practicing physicians and should be considered an integral part of regular health care encounters. This should include: (1) a review of smoking and exercise habits, and an estimate of obesity; (2) a careful measurement of blood pressure; (3) measurement of cholesterol; and (4) measurement of serum glucose concentration. The findings of such screening should be systematically reviewed with the patient.

B. Assessment of probability of near-term coronary events: One important, yet easy additional step in the standard health care evaluation by physicians could be the systematic assessment of the probability of the patient's developing a near-term coronary event. The data required for this probability assessment include only age, sex, blood pressure, smoking history, determination of serum cholesterol and serum glucose concentration and an electrocardiogram. From these data and the tables included in the American Heart Association Handbook on Risk Factors, a probability estimate for the subsequent near-term development of an overt coronary event can be derived in a few moments without calculation or computation. The cost of obtaining this information is exceedingly small relative to its value—and to other medical costs. The great value of this estimate lies in the increased awareness of personal health care it creates in both the physician and the patient, and in the personal incentive it provides for the person so demonstrated to be at increased risk to attend to the major abnormalities detected.

C. Financial consideration for screening costs: Screening costs could be borne by the individual and should be made part of each new patient examination and general physical review at specified intervals. However, it is clear that if cost could be reduced, a greater public acceptance could be anticipated. The feasibility of developing financial incentives to encourage the patient to seek such screening should be carefully examined.

These incentives might include the following: (1) Direct deduction of a reasonable, standard cost of the Health Screening Examination from the taxable income, allowable by appropriate documentation. This documentation could be provided by the physician utilizing a standard reporting form similar to those utilized for insurance purposes. (2) Reduction of life insurance premiums upon receipt of documentation of such an examination, with further reduction if cigarettes are not smoked or smoking is abandoned, weight is kept at optimal levels, and hypertension or hyperlipidemia effectively treated if present. If all risk factors are optimal at examination, premiums could be reduced accordingly. (3) Health insurance policies could offer payment to the physician for such defined health screening on an outpatient basis at specified intervals.

D. The cost of effective risk factor intervention: The cost and recoverability of intervention efforts is a significant question that will require careful investigation. Many physicians do not have sufficient time for detailed counseling on smoking cessation, proper dietary habits, proper exercise, and so forth. In some cases, to achieve these goals, more office personnel, space and materials would be needed. It is recognized that all require funding above and beyond funds now committed for health care. In the short term, medical costs would rise. In time this expenditure should be recovered with interest as prevention of atherosclerosis begins to occur. As an alternative and complementary to this expansion of physician office capability, special community "Risk Factor Intervention Clinics" may be needed to aid physicians in this effort. These clinics could serve as referral facilities where patients could receive counseling on diet, smoking cessation, exercise training or other behavior modification, when such expertise, time and space are unavailable in the physician's own office. Clinical development, sponsorship and operation require careful thought; if done in proper consultation with the practicing physician, nonphysician clinics (possibly in hospital outpatient departments) staffed by appropriate health care professionals could function in an efficient manner.

Major carriers of health care insurance, including Medicare and Medicaid, should be strongly encouraged to provide special recognition of the importance of these efforts in preventive health care. It should prove to be both effective and economic for such recognition to take the form of payment for such outpatient services when carried out in a defined and standardized manner.

V. What the Physician Should Teach

This Bethesda Conference should initiate the most important national health care campaign for the 1980s and provide the basis for a major reduction in coronary heart disease, the nation's leading killer. This project should parallel the National High Blood Pressure Educational Program of 1970, but should surpass it in importance and comprehensiveness.

Despite great national and international scientific interest in the concept of risk factors for atherosclerosis, and considerable public interest and activity, there remains a lack of general understanding of these factors, their relationship to atherosclerosis and coronary heart disease and the fact that they are remediable. To an

important degree, this lack of sophistication extends to many members of the medical profession. To achieve the educational goals regarding coronary risk factors, simultaneous, coordinated campaigns aimed at all physicians (not only primary physicians) and other medical professionals, as well as at the general public, should be initiated, perhaps using as a model the National High Blood Pressure Educational Program. *The message, to be simply and clearly transmitted, includes:*

A. There is a continuing major national epidemic of atherosclerosis and coronary heart disease resulting in death or severe disability for millions of Americans each year.

B. In a great many persons, death or disability occurs prematurely during the "prime of life," and in a substantial number during youthful years.

C. There is convincing evidence that atherosclerosis has many predisposing features. Prominent are the five remediable risk factors: cigarette smoking, hypertension, high blood cholesterol, physical inactivity and obesity.

D. There is strong evidence that if these five risk factors are controlled by appropriate modification of life style, death and disability from coronary heart disease can be sharply reduced.

E. The individual citizen bears the responsibility for his or her own general health care regarding cessation of cigarette smoking, optimal exercise, weight control, proper diet (including appropriate attention to fat, cholesterol, sodium and calories) and the monitoring of blood pressure. This should be a "People's War" not a "Doctor's War" on coronary disease, although supported by all physicians in every way.

F. Medical responsibility includes educating the public (and patients) about risk factors and their control, and the development of systems for their efficient detection and control.

VI. Methods for Patient Education

Four broad strategies in this public health effort involve the individual physician in the office:

A. Physicians should be encouraged to examine their personal behavior and life style, to identify and control recognizable risk factors for coronary heart disease.

B. Physicians should recognize that they and their families are regarded by the community as role models in matters of health.

C. *Physicians should be encouraged to develop the office as an effective health teaching forum, setting an example for the community.* Office personnel should be instructed about risk factors and encouraged to control them. The waiting room should reflect the concern of the physician and the staff for sound health practices in appropriate posters, informational pamphlets and booklets, use of "Thank You For Not Smoking" signs, and absence of ashtrays. Material "personalized" by the individual physician and developed to meet the individual needs of his patients is most effective. For example, a videotape produced for national distribution, carefully planned for patients or lay groups, could be modified to include a "lead in" tape of the individual physician, communicating his commitment to the program content of the tape. The impact to that physician's patients and the probability of use by the physician would be increased. When possible, space should be set aside for patient instructional modules, where audiovisual materials can be utilized effectively: slide-sound shows, videotape or film cassettes, television tapes, anatomic displays or poster displays, pamphlets, and so forth.

D. *All physicians should be strongly encouraged to adopt a systematic periodic review of major risk factors with each patient as part of routine practice.* The results of this screening should be transmitted to the patient in such a manner as to educate as well as to inform. As described earlier in this report the determination of probability of early coronary events from the data obtained at screening is a powerful education tool. This effort might be facilitated by special worksheets and report forms designed for the physician's office.

E. *Development of a special physician's kit should be carefully investigated;* this might include a concise scientific review of risk factors for the physician and office staff; posters and pamphlets for waiting rooms and examining rooms; slides-and-sound for synchronized presentations; worksheets; report sheets; American Heart Association booklets such as one on risk factors, and so forth. Kits developed on a national level and made available at cost (or partial cost) to the physician, promoted by concerned professional groups including the American Medical Association, the various state medical societies, the American College of Cardiology, the American Heart Association, the American College of Physicians, the American Academy of Family Practice, the American Academy of Pediatrics and the American College of Chest Physicians, and others would enhance the uniformity of the message transmitted.

F. The basic concepts presented should be consistent with in-hospital teaching and general community educational messages.

G. *Development of "model teaching offices" in strategically located cities should be investigated.* These could serve as "field laboratories" to implement and evaluate teaching aids and strategies. They could be developed in conjunction with medical schools and teaching hospitals or by private physician groups; and they should be appropriately staffed and equipped to simulate the private physician's office. They should have space for patient education, with suitable audiovisual equipment and educational material development and/or in "field-testing" prepared materials. Careful follow-up should allow accurate documentation of the effectiveness of this model in risk intervention.

H. *Nonphysician Model Intervention Clinics* could be established in carefully chosen areas to identify patterns of use and to explore more fully the usefulness of this approach. Careful attention should be given to optimal interaction between the physicians of the

community, the hospital and paramedical personnel in the planning and supervision of these clinics.

VII. Recommendations

Recognizing the wide prevalence of coronary heart disease and the scientific rationale for decreasing its incidence by modification of key coronary risk factors, this Task Force recommends that an intensive effort be made to enlist the physician in an all-out national campaign in the 1980s to reduce these health hazards. In order to develop and implement this effort, and continuing the impetus generated by this Bethesda Conference, the leadership of the American College of Cardiology and the American Heart Association should organize a national Steering Committee including members from appropriate medical, professional, voluntary and governmental agencies to:

A. *Develop a detailed program on educating and enlisting the physician in risk factor modification.* This should include stimulation of state, county and local efforts to reach the physician.

B. *Help develop educational aids for the physician* to carry out patient risk factor reduction in the office.

C. *Develop a guide for the physician strategy in risk factor reduction in the office including:*

1. The personal role model of physician and his family.
2. The development of the physician's office and staff as additional role models (no smoking, for example).
3. The development of the physician's office as an education center.
4. Risk factor assessment as part of routine and periodic contact with patients.
5. The derivation of the probability of a near-term coronary event for selective patients for their education and enhancement of incentive for control of undesirable risk factors.
6. Utilization of community resources—nutritional guidance, quit-smoking clinics, hospital outpatient programs, weight control groups.

D. *Establish programs to develop and evaluate mechanism for financial support of this endeavor* and to evaluate the results of such risk factor intervention programs.

Task Force 3: The Physician in the Work Setting (Industrial/Occupational Medicine)

ROBERT S. ELIOT, MD, FACC, (CHAIRMAN), MARCUS B. BOND, MD, ROBERT O. BRANDENBURG, MD, FACC, THEODORE COOPER, MD, FACC, JOSEPH L. CRUMRINE, MD, MELVIN A. GLASSER, DUDLEY HAFNER, J. ALAN HERD, MD, GENE E. HOLLEN, LORIN E. KERR, MD, ROBERT SHERWIN, MD, LEON RESNEKOV, MD, FACC, NORBERT J. ROBERTS, MD, HENRY E. SIMMONS, MD, ROBERT D. SPARKS, MD, STEPHEN M. WEISS, PhD

I. Introduction

Coronary heart disease still accounts for more premature deaths than any other disease in the industrialized world. It is more humane, more economic and more practical to emphasize prevention of this disease than to try only to cure it.

The recent declines in deaths due to coronary and cardiovascular disease are generally believed to result to some degree from improved health behavior on the part of the public. Significant factors contributing to this phenomenon appear to be: (1) control of high blood pressure, (2) reduced cigarette smoking, (3) improved nutrition with resultant reduction in serum cholesterol levels, and (4) increased exercise. Other factors believed to have important value in controlling this disease include weight reduction, stress management and the modification of so-called coronary prone behavior.

This report assigns priorities to risk factor control based on an operational, best-judgment estimate of present-day ability to implement this effort in the workplace. Both the body of scientific evidence and the body of practical experience underlying these recommendations are bound to evolve, with resultant enrichment and refinement of goals and methods in the years ahead. Where scientific debate is current, approaches are proposed that are deemed sound, safe, feasible and useful, hence reasonable to pursue as components of this program. It is the goal of this Task Force to provide methods by which coronary heart disease may be reduced by implementation in the occupational setting of widely accepted preventive programs. The major goals are the establishment of health programs for all employees and suitable changes in the work environment.

The work setting should be seen as uniquely suitable or this disease prevention program. It provides direct ccess to a large number of people, currently some 90 illion workers. It offers the potential for reasonable ontinuing availability of the group, thus making pos- ble essential follow-up activities in ongoing pro- rams.

In the workplace, consideration must also be given o complementary activity related to exposure to po- ntially hazardous conditions that may have to be dealt ith as part of a preventive medicine program. These ıcludes stress, exposure to potentially hazardous ıbstances and other dangerous working conditions. It important that recognition be given to reducing and ventually eliminating from the workplace the haz- rdous substances and conditions known or believed to ontribute to the development of heart disease. These eed to be dealt with as part of a total program. Since ıey involve another set of considerations they are not ealt with in this presentation.

The workplace also makes possible the development f social support systems, through cooperation of labor nions, ethnic societies, social and recreational orga- izations that can help organize such programs, pro- ıote them and encourage continuing participation of orkers within them. Such programs also provide the otential for needed financial support through employer ayments, collective bargaining agreements or other ıutually agreed upon methods.

There are drawbacks to the workplace that should e identified and resolved. These include worker con- erns about the confidentiality of their medical records, rincipally because of possible threats to their job se- urity, and suspicion about the motivation of some mployer personnel or medical departments, or both, ı promoting such programs. Employers may resist ealth promotion programs because of potential costs. ı some medical communities there may be opposition y physicians because of perceived threats, whether real r imagined, to private practices.

A central question deals with why the work setting selected for special attention. In fact, the over- helming majority of physician-patient encounters ccur in the individual doctor's office. As important as ıese encounters are potentially for the preventive ef- ort (see report of Task Force 2), at least two facts in- icate the merit of emphasizing the role of the work- lace: (1) Large numbers of workers do not see their octors regularly except for the treatment of episodic lness; and (2) present reimbursement methods by third art payers usually do not cover preventive services.

Although the cost of such programs needs to be de- rmined, it is generally recognized that there is in- easing corporate interest in supporting and expanding ealth programs for employees. Health promotion ac- vities such as those outlined by this Task Force are med at the development of individual responsibility r health by participating employees and the en- ancement of the occupational setting as an adjunct to lving health problems and to health promotion. The ome also is an important occupational setting and may e reached through the employee in the work setting.

The demonstration of effective model programs is seen as having a potential ripple effect throughout American industry, and a potentially favorable economic impact due to the improved image of the workplace by the demonstrated concern of management for employees. The related incentives are independent of an immediate need to demonstrate cost effectiveness, reduced catastrophic illness and disability, reduced absenteeism, and so forth.

Role of the physician: The obvious assumption is that the physician has a role in the work setting in preventing coronary heart disease. It is also assumed that employees will benefit by the care and direction the physician can provide for the prevention of heart disease. This is true whether the action of the physician is direct or indirect through other health workers under his or her supervision. It is also recognized that the physician can influence institutional practices or the environment which may be contributing to the occurrence of heart disease. The goal of this report is to identify the most effective health promotion techniques for the prevention of coronary heart disease.

The increase in the cost of treatment argues for rational health promotion and disease prevention programs. Young employees come to the workplace with new and different goals and priorities, and with a higher level of social awareness. Concern for humanistic interest on the part of employers bodes well for enhanced work performance of employees who participate in such programs.

There are approximately 5 million work sites throughout the nation. Of these, about 14,000 work sites employ more than 500 workers. These account for approximately 25 percent of the 90 million civilian workers. The other 75 percent of workers are employed at plants with fewer than 500 workers. Of these, 85 percent employ fewer than 25 people. The importance of these statistics is that 2,500 physicians are employed full time in occupational medicine and nearly all of them work in plants that have more than 500 workers. About one fourth of these physicians are administrators, without direct responsibilities for patients. Another 10,000 physicians work part-time. Again, they are to be found mostly in settings employing more than 500 workers. There is rarely an occupational health service in plants employing fewer than 500 workers.

Any proposal for coronary prevention activities at the workplace must consider the diversity of the American occupational setting, the diversity of jobs in these settings, and the proposed delivery system most appropriate to the institution in question. To provide the most feasible solution for an occupational setting based on this report requires the establishment of priorities and methods for health promotion most appropriate to and feasible with the particular workplace.

II. Goals and Objectives

The goal of this Task Force is to point out the importance of the physician's role in the work setting and the manner in which his or her effectiveness can be increased in the prevention of coronary heart disease. The following goals and objectives are considered general

guides for individual programs outlined in later portions of this report. *The Health Promotion program should:*

1. Consider all levels of management, labor and health providers in the occupational setting, involving the spouse and family where possible. Recognize that work in the home setting is an occupation and that interest and adherence on the part of those in the home setting are important supports for the entire program.
2. Identify the specific disease prevention needs of participants.
3. Identify and define various types of participants.
4. Identify feasible models of health promotion in relation to those risks deemed important in the prevention of coronary heart disease.
5. Outline the roles of industry, physicians and employees and their organizations in the development and support of these programs.
6. Establish reasonable expectations for management, labor and physicians with regard to the success of this program.
7. Design and implement feasible programs.
8. Evaluate effects of programs for disease prevention.

Specific issues to be addressed include:

1. Definition of the proposed benefits.
2. Communication of the apparent benefits of the program.
3. Program administration.
4. Effective and efficient utilization of medical and health personnel.
5. Necessary equipment, facilities or services for the implementation of such a program.
6. Location, character and responsibilities of in-plant medicine.
7. Monitoring and controlling the adequacy of occupational medicine with regard to this program.
8. Motivation of health professionals to perform in accordance with the desired role.
9. Gaining the acceptance of workers for the health enhancement program and ensuring their continued participation, enthusiasm and adherence.
10. Education of employers and third party payers with regard to the importance of financing health promotion programs and services of this type at the worksite and in the community.
11. Increase productivity and diminish self-destructive behavior.
12. Determine the cost effectiveness and social benefits, while recognizing the focus on longer life with better health, that is, on the quality of life.

A. The Role of the Physician

As indicated earlier, physicians who provide medical care and health services for employees may be full-time or part-time workers or consultants. Such physicians respond to various needs of the population of workers within a great variety of occupational settings. Each setting has its unique goals and objectives. It is important that the health promotion program take into balanced consideration the need to develop a synergistic relationship between the goals and objectives of a corporation and those of its employees and occupational medical people.

The role of the physician is complex, involving the evaluation and implementation of scientific evidence as it emerges from careful and well controlled clinical trials, clinical investigations and basic research. The physician must promote the health of employees on the basis of current, scientifically valued medical and health information and must be convinced that the proposed program for education and intervention is important and effective. In the occupational setting, it is reasonable that activities for health promotion should be attempted that have the highest likelihood of visible success. Acceptance of health promotion is more likely if a small number of potentially valuable services be phased in rather than swept into existence. Each program should have careful monitoring and evaluation systems appropriate to its specific needs.

B. The Physician's Perspective

The physician's view of a program is that prevention of coronary artery disease presents an opportunity to decrease morbidity and mortality in specific groups of people. The opportunity for physicians goes beyond that purpose in several instances:

1. *Occupational physicians* are charged with advising employers on the maintenance of safe and healthful working conditions and performing health evaluations and on site health care, as well as other duties. The new dimension is that of health promotion, which incorporates an expanded educational role in addition to traditional health services.
2. *Public health physicians* may also be involved because of their concerns for regulations, public and professional education and administration of special health programs.
3. *Health maintenance organizations* may establish liaisons with business and industry and provide quality health care for populations at a reasonable cost.
4. *Family physicians* unrelated to full-time occupational settings are concerned with the health and morale of their individual patients.
5. *Biomedical scientists* studying the epidemiology, etiology, pathogenesis and treatment of heart disease and the rehabilitation of patients with disability from chronic coronary heart disease may become involved to elucidate opportunities and benefits for health promotion and disease prevention.
6. *Medical educators* may participate to teach principles of prevention and treatment and to provide clinical experience for students in the health professions.
7. *Cardiologists* participate to prevent cardiovascular disease and rehabilitate patients with coronary heart disease and other forms of cardiovascular disease.

All these illustrations identify the wide variety of physicians available for evaluation and implementation of the principles and programs espoused by the consensus of this conference. It is also important for phy-

sicians periodically to appraise and evaluate the success of a program.

Physicians will be aided by education in preventive cardiology. Components of the education should include: the data base for prevention of heart disease; epidemiology; program designs including organization, education and evaluation; technologic aides for retrieval of data; organization of resources; program implementation; evaluation.

Armed with the aforementioned abilities, physicians can have an important impact in: (1) public relations with participants; (2) professional relations with other physicians and health care professionals; (3) advocacy and persuasion; (4) technical services for early detection, diagnosis, treatment and rehabilitation; (5) expert knowledge; (6) educational resources; (7) appropriate referral; (8) designing, implementation and management of specific programs; and (9) research and evaluation of programs in order to provide industry and organized labor with a better sense of direction for program developments and cost effectiveness in coronary heart disease prevention.

C. Perceptions of Participants

It is important to realize that participants will need to know a considerable amount about the program in order to be motivated to participate. What are the presumed benefits? How do we best communicate the apparent benefits of the program and make it easily understood by the potential beneficiaries? How is the prevention program to be administered and conducted within the goals, objectives and functions of the occupational setting in question? As implemented, what is the role of physicians and allied health personnel? What is an effective follow-up mechanism to evaluate and communicate the impact and to make necessary modifications in the program?

Participants will be concerned about certain ethical medical practices and principles. Many of the programs will be educational in nature and do not involve the delivery of any form of medical or health care. In some areas, however, the programs will be prescriptive in nature. The programs will be voluntary and thus informed consent for the limits of the program will be a requirement in which the conditions and "risks" of participation are carefully spelled out. The possible distinction between the individual benefits and population benefits on the basis of control of risk factors also should be part of informed consent. Participants will be encouraged that the program entails no negative, unpleasant or harmful experiences or consequences beyond that of education and selective medical treatment as indicated. The program should be planned, conducted and evaluated by qualified experts in conjunction with representatives from labor and management. Again, it should be based on a clear understanding of the difference between conditions that are associated with or contribute to an illness and those that cause it.

III. Operational Perspectives

The remaining part of this report is divided into two main sections: Program Administration and Health Promotion Programs. The first section is designed to provide a framework in which a program can be administered in the work setting. The second section suggests specific health promotion programs that can be selected for use within the framework.

IV. Program Administration

A. Target Groups

To develop an effective employee health enhancement program, the cooperation and input of the following groups must be obtained: management, union management, medical staff and the employees (both wage and salary).

1. Management: The goals and objectives, potential benefits and evaluation systems have been outlined in the foregoing sections.

2. Medical staff: The medical department should be given responsibilities in the planning and in the implementation of the program. The large majority of employees will be asymptomatic with a wide range of indications for future health. It is to this group that the program must appeal since they will make lifestyle changes because of the value of the changes to them personally and not because they live in fear of becoming ill. Positive reinforcement is a strong motivational force.

Within any employee group, as outlined earlier, there will be a sizeable percentage of employees who demonstrate risk factors. These employees should be counseled and examined or referred for treatment, or both, by the medical director or his staff or by other local physicians. They should be motivated to change by the normal patient-physician relationship or be turned back to the general program to concentrate on individual lifestyle changes deemed most appropriate to reducing the risk factors identified in that patient by the physician.

3. Employees: Lifestyle changes cannot be legislated by management. Employees must understand the importance of lifestyle change and determine the importance of these changes to them personally. The planned program must create a sense of involvement and allow employees to make progress by their participation. Establishing mileposts and guidelines which can be achieved by participants is an additional powerful motivating force. The program must overcome the general employee feeling that "it won't happen to me." Statistics are a basis for predicting that it will happen to a predetermined percentage.

B. Strategy

The strategy for an effective employee health enhancement program requires three types of change.

1. Environmental change: Changes of the work environment that provide support to employees desiring to change their lifestyle as well as programs to eliminate

from the workplace those substances or circumstances likely to add to health hazards of exposed employees are of key importance. Improved food in the company cafeteria, fruit instead of junk food in vending machines, a place to exercise and shower, a smoking policy, promotional material, including a bulletin board to display current articles on health, are a few methods that have proved valuable in the experience of Johnson and Johnson, for example. These changes are highly visible to both managers and employees. They also serve as a constant reminder or feedback of the importance of lifestyle change. They also allow employees to watch the participation of other employees. In some cases, if the right employees get involved, a number of other employees will follow. This is an important educational technique referred to as modeling. Key individuals in management or labor may serve as motivational models by their actions which, indeed, speak louder than words.

2. Intrapersonal change: Individuals should begin by examining their own lifestyles and deciding on the changes that they personally believe need attention. Environmental changes will help support this effort.

3. Interpersonal: Because of the close association of employees in most work settings, there is a support function that occurs between employees trying to make similar lifestyle changes. Oftentimes they may jog together at lunch time or provide support to each other if they are trying to stop smoking or lose weight.

The synergism of these three types of activity in the work setting provides the opportunity to maximize lifestyle change among employees. Once this activity is well under way, an attempt to institutionalize the activity should be made. Plans for next year' program should coordinate with the company's cycle: planning, budgeting, implementing and evaluating.

Strategically, the above described effort will gradually provide a program of primary prevention. Secondary prevention should be practiced for those employees who have major cardiovascular illnesses and are returning to the workplace.

C. Program Criteria

The above strategy puts heavy emphasis on creating support systems within the workplace to aid in individual lifestyle change. To implement this program effectively, the following criteria are of value. The program should be:

1. *Voluntary:* There is no need for management pressure, but management participation is essential.
2. *Based on sound scientific and medical data.*
3. *Designed to provide freedom of choice programs.*
4. *Sustained over time rather than brief campaign activity,* that is, sustained follow-up for sustained participation.
5. *Focused on health enhancement and improved quality of life* rather than diagnostically oriented; it should not use scare tactics or blame as a motivator; positive reinforcement is more powerful.
6. *Evaluated at intervals for measurable results.*
7. *Flexible and adaptable to individual differences* and special *needs* for certain work units.
8. *Cost effective* over the long term.
9. *Evaluated with follow-up* of workers needing additional diagnosis or therapy, or both.

D. Health Screening

The measurement of an individual's lifestyle and biometrics through health screening provides an opportunity both to educate and to motivate the employee to lifestyle change.

1. Personal questionnaire: A large amount of information to help employees change lifestyle is available for the asking. A questionnaire covering medical history and personal habits (smoking, drinking, exercise, stress and nutrition practices) provides an excellent starting point.

This information should be collected confidentially. It is important for the employee to know that this information is for his value and no one else. If this confidence is violated, participation in the program will probably decline. The collection of this information will force the employee to think about health habits more carefully.

2. Biometrics: A record of measurements such as height, weight, blood pressure (diastolic and systolic), cholesterol, high density lipoproteins, pulse rate, and so forth will provide a quick overview of the employee's health. During the time this information is being collected, employees should be educated about the meaning of each measurement. Review of health habits from the questionnaire and of the biometric data provides the necessary information to analyze each participant and identify indications for future health.

3. Employee feedback: This analysis should be returned in a confidential manner to the employee. Areas for improvement should be suggested to the employee. This information will clearly indicate what needs to be done. Employees must be assured that the information obtained from such studies will not be used to jeopardize the job, seniority or opportunities for advancement.

Employees should be encouraged to seek advice about this feedback from the medical director and his staff or their personal physicians. Community programs to stop smoking; promote exercise; improve nutrition to prevent or control hyperlipidemia, obesity, hypertension, diabetes and to reduce stress are available from a variety of sources. The same is true of preventing or controlling alcohol abuse. Employees should be encouraged to enroll in these programs where improvement is required.

4. Correction of defects: No screening program should be initiated in the absence of a program designed to correct or adequately treat reported defects.

E. Evaluation

Summary tables of personal and biometric information for groups will provide an overview for the planning group with regard to the indications for health of all

participants. An analysis of this material will suggest those areas that are most in need of improvement.

Health screens that are conducted annually will provide comparisons with the previous year so that changes in the population can be determined. In a similar manner, if employees are given proper feedback, they will be able to determine the changes in both lifestyle and biometrics from their original health screen, as a group and—confidentially—as individuals.

An economic evaluation can be made by determining the changes in those factors outlined under the management section and then determining the value of those changes. As an example, if cigarette smoking was reduced by 30 percent during the year, a drop in absenteeism and in medical claims among the original smokers should be observed. The economic benefits of these changes should be computed. In a like manner, a group of employees who start exercising aerobically on a regular basis may find that they have less flu, upper respiratory infections and so forth during the year. In addition, there may be a reduction in the number of days away from work.

Based on the initial interest of employees in positive health programs, it may be possible to show that participants in the program have less turnover. If true, this would reduce hiring, training and separation expense.

F. Occupational Health and Safety

The above described activities should not be confused with the need or responsibility to improve safety and free the workplace of occupational health hazards. A medical director or consultant may assume this responsibility. The same person may be a logical advisor and supporter of the health enhancement program, including advising employees found to be at risk.

G. Summary

As outlined in the operational perspectives above, there is a substantial opportunity to reduce heart disease in the general public and at the same time to begin to counter the rapidly increasing cost of health care. The workplace presents one place to begin a health enhancement program. An annual health screening examination provides an opportunity to monitor progress of employees and to continue to motivate them. Once substantial numbers of employees have become involved, the effectiveness of the program will continue to increase. It can extend from a workplace to the home and from the home to the community. Over time, living healthy lifestyles should become a way of life.

V. Health Promotion Programs

Each of the individual programs for health enhancement can be envisioned under the supervision of a health enhancement advisory committee. The committee would be composed of key management, labor and medical personnel. The risk factors in coronary heart disease have been graded in priority for intervention on the basis of an operational estimate of present-day ability to influence them at the workplace. The American Heart Association and other community-based organizations can provide guidance and materials for the development of programs.

Priorities are ranked as follows:

A. Control of high blood pressure.

B. Reduction of cigarette smoking.

C. Improvement of nutrition for management and prevention of hyperlipidemia, overweight, high blood pressure and maturity-onset-diabetes.

D. Modification of coronary-prone behavior and stress management.

E. Increased exercise.

F. Control of alcohol abuse.

Each of these programs is discussed from the point of view of background, purpose, objectives, operating principles for implementation, services and evaluation.

A. Program: Control of High Blood Pressure

1. Background: A major national study sponsored by the National Heart, Lung, and Blood Institute in cooperation with the private sector has clearly indicated the value of identifying and controlling high blood pressure.[1,2] The impact of high blood pressure on a variety of cardiovascular diseases is indicated by the nearly 40 million Americans who have elevated blood pressure and the remarkable increase in risk that this condition creates in its uncontrolled form. Even minor or transient elevations of blood pressure are now identified as major contributors to coronary heart disease. Moreover, the means are now at hand to identify and control this most pervasive but assessable health risk.

2. Purpose: The purpose of this program is to reduce death and disability as a result of premature cardiovascular disease by the detection of high blood pressure in employees, by educating employees to the nature of high blood pressure and its management through pharmacological and nonpharmacological methods and by the continuing evaluation and reevaluation with individual counseling as deemed necessary and appropriate to individual cases.

3. Objective: The objective is to develop self-management potential through educating the individual by a variety of techniques. The incentive for control of high blood pressure is oriented toward delegating further authority for self-management to the hypertensive individual as that person demonstrates his or her ability for self-management.

4. Operational principles for implementation: Screening programs are well outlined by the National High Blood Pressure Education Program[3] and will not be discussed in this report. After initial screening or identification of the hypertensive person, it will be necessary to decide whether medical treatment will be provided by the corporation through the offices of its medical staff or by a private physician. At this point, the participant will enter the service portion of this program.

5. Services: It is strongly recommended that the participant receive an educational background through seminars conducted by health educators on an intramural or extramural basis. Intramural activities for

the control of high blood pressure are preferable. Educational materials, posters, reminders and individual counseling help to reinforce the importance of managing the disease that remains silent until a complication develops.

The pharmacologic management of the participant is best provided through the high blood pressure control guidelines under the principles of "Stepped Care".[4] Hypertensive participants can also benefit from nutritional counseling for weight control, salt restriction, avoidance of heavy drinking, and so forth. For the cigarette-smoking hypertensive person, there is increased risk and *smoking cessation* can be an additional benefit. Occasionally, the person with early hypertension will obtain value from exercise conditioning, and exercise may aid in weight control.

The program is organized as follows:

a. Identification of hypertensive patients will usually occur at the periodic physical examination. Baselines studies should include: (1) History and physical examination. (2) Chest X-ray film. (3) Electrocardiogram (12 lead). (4) Urinary analysis (microscopic). (5) Serum creatinine, potassium, cholesterol, uric acid and glucose determinations. (6) Assessment of additional risk factors that multiply the risk in the hypertensive person.

b. Consultations: To include the options available after outlining the degree of severity, extent of the problem and associated risks as well as the therapeutic goals of autonomy with self-management.

c. The options include: (1) The full in-house program implying both pharmacologic and nonpharmacologic components. (2) Total management by a private physician, outside health group, Health Maintenance Organization, public health group, or hospital outpatient service of the participant's choice. (3) Pharmacologic management by the local private physician, nonpharmacologic management by the corporate health promotion staff. (4) Medical management by the corporate health promotion staff without nonpharmacologic service. (5) No treatment.

For those who opt for any form of in-house managed pharmacologic therapy, the physician in charge must be highly sensitive to any perceived side effects that, by themselves, could diminish adherence. For those who opt for nonpharmacologic management within the employee health program, special attention will be paid to instruction and demonstrations in the following (where deemed appropriate): relaxation techniques; noncultist meditative techniques; nutritional counseling for sodium content of common foods; nutritional counseling for weight control where necessary; counseling for alcohol control where necessary; assertiveness training; exercise conditioning; and others as appropriate. The above functions should include the spouse where appropriate.

d. Failures: For those whose hypertension is not controlled despite adequate pharmacologic attempts, further investigative studies such as X-ray urography should be considered among other possibilities. When nonadherence appears to be the reason for control failure, special counseling and behavioral modification methods may be of value.

e. Incentive: For those who achieve autonomous control as defined by periodic checkups, a special incentive might be offered. This could consist of a high-level health awareness, promotion and stress management program provided to the successful patient and spouse at a retreat-like location.

The program might include: (1) Lectures on key subjects related to improved coping mechanisms, leisure activities (use and abuse), sexual problems, family problems, advanced nutrition and so forth. (2) Workshops or lecture topics for small groups. (3) Food preparation demonstrations. (4) Exercise and leisure counseling. (5) Free time. (6) Entertainment. It is anticipated that proper information in the hands of employees and spouses will serve as feedback to the company and to motivate other employees.

6. Evaluation: In hypertension, the risk is well accepted and well known. The effectiveness of therapy is easily measured by simple checkups and the effectiveness of the different therapy groups can also be assessed. Evaluation of the control of hypertension is a reasonably straightforward process requiring minimal equipment (blood pressure cuff) and can be part of routine evaluation by allied health personnel.

B. Program: Smoking Cessation

1. Background: The influence of cigarette smoking is one which directly relates the number of cigarettes to the incidence of coronary heart disease and sudden death.[5–8] In addition, there is strong evidence to support the influence of cigarette smoking in carcinoma of the lung as well as in chronic lung disease such as emphysema, bronchitis, bronchiectasis, high incidence of upper respiratory infection, and so on. Little question exists with regard to the value of cessation of cigarette smoking.

There are numerous smoking cessation programs available to industries from community, public and private organizations. The specific set of employee needs of each work setting will determine the type of program chosen. For purposes of this report, a cessation program that uses cognitive and behavioral methods is discussed. Aversive techniques are not included, although they are available from community resources. There has been much debate as to whether smoking is a habit or an addiction. The program described here deals with smoking as a behavioral problem, that is, breaking habit patterns rather than a pathophysiologic addiction to nicotine.

2. Purpose: The purpose is through a variety of techniques to reduce the number of employees who smoke cigarettes.

3. Objective: By reducing the number of cigarettes smoked and the number of smokers, to reduce the incidence of diseases of the heart and blood vessels as well as those of the lungs, including cancer of the lung, upper respiratory infections and chronic lung diseases. In addition, there are some "fallout" benefits such as reduced hostility between smokers and nonsmokers.

4. Operational principles for implementation: One cannot underestimate the potential effect some of the more practical factors have on the success of smoking cessation programs. If at all possible, the program should be offered to both employees and their dependents. Ideally, programs should be held for small groups of 8 to 15 people with one or two leaders. The room should offer a comfortable environment, be well ventilated and arranged in a manner conducive to discussion and sharing.

Sessions should be conducted before or after hours or during lunch hours. This is consistent with the voluntary aspects of the program and tends to demonstrate an attempt on the part of the employee to change behavior. As an added support, the employer should consider a no-smoking policy in certain areas of the premises. This policy may include the removal of cigarette machines from the work setting.

Smoking cessation is a very complex behavioral program. Most programs run for 6 to 8 weeks, meeting once a week for 1 to 2 hours. The advantage of weekly sessions is that employees have the opportunity to practice a new learned behavior while gradually withdrawing from their smoking habit. Six weeks is a minimal time frame for the actual program content to be provided. Of equal importance is the provision of reinforcement for 6 to 12 months after the program, with particular emphasis on the first 3 months. The methodology of this reinforcement is described in a later section.

Publicity for a smoking cessation program can be done by traditional methods of fliers, posters and desk drops. However, the most successful methods are those that utilize well established channels of opinion, such as labor organizations, employee leaders, regularly scheduled safety meetings or that elicit the support of management at varying levels.

Staff for the smoking cessation program should be recruited from the existing health personnel of the industry. This not only facilitates regular repetition of the programs but also provides continuity with employees over time. When professional resources are not available internally, contracts with local, public and private organizations can be arranged. Another possibility is to have employees who are ex-smokers conduct the program.

The professional resources are the basic support system for the smoking cessation programs. They should be either self-trained or have received some outside training. Training requires both reading, discussion and practice. Several of the references listed at the end of this paper are of value in self-training.[9–11] Community agencies such as the American Cancer Society also offer training. Ideally, the leaders should be ex-smokers; however, persons who have never smoked can successfully conduct programs. The presence of the smoking habit among health professionals continues to be a real barrier to the initiation of these programs.[12] One cannot underestimate the importance of a good role model.

There are several teaching techniques available for use in smoking cessation programs. Most programs are set up as group efforts to reach the maximal number of employees (and dependents). Groups provide the additional opportunity for participants to share experiences and effectively use peer pressure and support to reinforce new habit patterns. For each group member to have the opportunity to speak, the size should be kept small and coincide with the allowed time frame.[12]

5. Services: There are basically three types of teaching methods used in smoking cessation programs: cognitive, behavioral and aversive. The first method, cognitive, requires the employees individually to identify why they started smoking, why they currently smoke, what is pleasurable and distasteful about the habit, and/or why they want and do not want to stop. This is accomplished through list-making and discussion. The detrimental health aspects are sometimes discussed, but in general the population is well versed in this line of reasoning. Written and audiovisual resources may be used to stimulate or reinforce the discussion.[12]

The next step in the cessation process is to identify patterns in the individual's smoking habits. This usually is accomplished through daily record-keeping practice. The employee records some or all of the following: the time, place, mood, what was being done or with whom, the level of the need,[9] urge[10] or craving[11] to smoke. This latter recording is usually a rating scale of 1 to 3 or 1 to 5. The discussion then focuses on the behavioral patterns that are illustrated in this record and how the participant can begin to change these patterns by substituting a response that does not include smoking. In some programs, the change is oriented more toward problem solving,[10] in others toward a disruption of the habit sequence.[11]

At this point, the behavioral aspects of the program become more prominent. The scientific theory behind changing behavioral patterns is that the participant must learn to recognize and control through practice/repetition: (a) the stimuli or cues that trigger the behavior; (b) the response, smoking of a cigarette, or the urge; and (c) the reinforcement or consequences of this behavioral response. From this point on, the teaching methods focus on changing the stimulus-response-reinforcement pattern. Generally, behavioral programs focus on a gradual reduction in the number of cigarettes smoked, with a targeted quit date during the program. The behavioral patterns are changed in order to facilitate reduction.

The following list summarizes some of the more common behavioral techniques used to aid participants in this process[9–11]:

Changing brands.

Keeping a daily smoking record (attached to cigarette package).

Using a large jar to collect cigarette butts.

Not stockpiling, only buying one pack of cigarettes at a time.

Scattering smoking materials around the house.

Not carrying matches or a lighter, so one has to ask others.

Changing the hand used for smoking.

Putting cigarette down between puffs.

Keeping a daily progress chart or graph.
Keeping a piggy bank for money saved.
Having ashtrays, house, clothes, teeth cleaned.
Throwing out extra cigarettes.
Written contract with friend, professional or group.

Probably the two most common methods used in reducing and quitting are not smoking in certain places (that is, the car, office, kitchen) and gradually eliminating cigarettes by starting with those that have the lowest rating of craving or need. There are other helpful adjuncts such as relaxation and mental imagery (positive and negative) which can be used. During each of the weeks when these behaviors are being changed, the emphasis of the group leader should be upon reinforcing and praising the positive achievements. Discussions of negative behavior or failure should not be emphasized, just accepted.[12]

During the new ex-smoker phase, it is important that the participants have one or more accessible persons for support, either a professional, friend or group. Group meetings, individual counseling sessions, phone call support, and so forth, are also successful if employed on a regular basis. Since most people resume smoking during the 1st month after quitting, programs that stop abruptly after 6 or 8 weeks will be less successful. Reinforcement should continue for a minimum of 3 to 6 months after the program.

6. Evaluation: Because of the proliferation of smoking cessation programs now offered to industry and their reported varying success rates, a sound evaluation is necessary to determine the success of a program.[12] For purposes of this discussion, evaluation is limited to self report through questionnaire administration. Blood or pulmonary testing are evaluative options but their additional cost must be carefully considered.

A suggested evaluation protocol would include the following items as a minimum: (1) A smoking history form should be given at the first session asking for information about the number of cigarettes smoked, number of years smoked, age, sex, job level, presence of smoking spouse (or significant other), previous attempts at cessation, and locations. (2) Follow-up questionnaires should be administered at 3, 6, 12, 18 and 24 month intervals to determine retention or change in habit. (3) Response ratios should not drop below 80 percent for any of the questionnaires. There are additional research questions which can be asked about attitudes, beliefs and dosage patterns, but the time burden on employees and professionals will increase.

The evaluation of a smoking cessation program should yield information about who is able to quit, problem areas in the program, the success rate, and possibly some cross comparisons among the many programs offered. The same protocol should be used for all the programs offered. The type of statistical analysis performed on the questionnaire data will vary according to each company's objectives. It is also advisable to determine the existing prevalence of smoking in the employee population before the initiation of cessation programs. The evaluation will then yield data on how close the industry is to eliminating this behavioral problem.

Smoking cessation programs are one of the most common health promotion components offered in the work setting. It is clear that this behavioral change yields positive health results. Over time, these programs should be of benefit not only to the individual but also to the company and its financial investment in its employees.

C. Program: Enhanced Nutrition and Weight Control

1. Background: Good nutrition has long been recognized as an important component in the maintenance of health and the prevention of disease. Malnutrition, both undernutrition and overnutrition, can contribute in various ways to disease processes. While the relationship between nutrition and cardiovascular disease is as yet not fully clear, some moderation in dietary intake seems warranted. Moderation in intake of certain foods high in calories, fat and salt is appropriate until direct cause and effect relationships in humans are determined.

Dietary Guidelines for Americans, published by the U.S. Department of Agriculture and the U.S. Department of Health, Education and Welfare, recommend eating a variety of foods, maintaining ideal weight, avoiding too much fat, saturated fat and cholesterol, eating foods with adequate starch and fiber, avoiding too much sugar, avoiding too much sodium, and consuming alcohol only in moderation.[13] The *Surgeon General's Report on Health Promotion and Disease Prevention* specifies sufficient calories to meet body needs and to maintain desirable weight with reduction in calories if overweight, less saturated fats and cholesterol, less salt, less refined and processed sugar, relatively more complex carbohydrates from whole grain products, cereals, fruits, and vegetables, and relatively more fish, poultry, legumes and less red meat.[14] Although recommendations of official organizations are indefinite, evidence converges towards the conclusion that altering diet, particularly for individuals with elevated serum cholesterol levels, may delay the progression of coronary arteriosclerosis. The strength, consistency and plausibility of this argument suggest that the aforementioned recommendations are sensible and safe.

Experience tells us that for many the immediate pleasures of eating are little affected by remote possibilities of coronary heart disease. Since final proof is not available concerning the benefits of healthful diets, we must balance costs, risk, benefits and effectiveness for each recommendation. There is also a responsibility to provide individuals with the facts they need to make intelligent choices and to present a balanced view of the issues.

2. Purpose: The purpose of the nutrition program is to foster and encourage better quality dietary intake and the development of new eating habits including moderate intakes of fat, calories, sugar, salt and alcohol, and optimal intake of all essential nutrients (vitamins, minerals, calories, and so forth).

3. Objective: A better quality dietary intake will aid

individuals in maintaining health and preventing disease.

4. Operational principles for implementation: The likelihood that a nutrition program will be successful and the measures for quantitating its success depend upon thorough evaluation of employees and the occupational setting before the program begins. Demographic characteristics should be determined, health and illness data assembled, and summaries of health care service utilization should be prepared. Any physical and laboratory data relevant to nutrition and coronary heart disease should be sought. The history of nutrition programs and other health promotion programs presently or previously in operation should be reviewed. If possible, the attitudes of decision makers, middle managers, white collar and blue collar employees to health promotion programs in general and nutrition programs in particular should be determined. Areas that must be addressed in a nutrition program include attitudes, knowledge and skills of participants; patterns of cafeteria food choices; and food purchasing patterns in local stores.

Many avenues are available for establishing visibility and spreading information for a nutrition program. Newsletters, posters, mailers, lectures and demonstration, special food service menus and food displays all can be useful. The opportunity to develop social and environmental situations favorable for nutrition programs should be sought through targeting of specific operational divisions for intensive efforts in promotion and recruitment.

A special concern for promotion and recruitment in any nutrition program is involvement of other members of families, especially the wives of male employees. Diet and eating habits are very much family concerns and food preparation usually is in the hands of wives of male employees. Women employees who prepare food for their own families also need the cooperation of their husbands. More than in any other health promotion program, involvement of families in nutrition is particularly important.

Efforts at the promotion of nutrition programs must be sustained over time. Success is likely to be proportional to the resources available for continuing promotion, developing visibility and establishing credibility. Publicity for case reports and success stories in weight control, testimonials concerning perceived benefits, displays of group benefits in reducing weight and lowering lipid and blood pressure levels, establishing awards and prizes for weight loss, and publishing health care utilization data all are important in maintaining momentum for a nutrition program. The greater the visibility and enthusiasm for a nutrition program the more success is likely.

5. Services: Nutrition education should take as many forms as possible. Families of employees must be involved whenever changes in eating habits are recommended. Printed materials and audiovisual materials can be made available to individuals and groups. Lectures, demonstrations and discussions with small groups on a regular basis concerning food purchase, food preparation and eating habits are the usual approach to establishing cohesive groups. Personal counseling by a registered dietitian can provide intensive efforts directed toward individuals of special concern. A basic education in nutrition is no guarantee for establishing sensible diets and eating habits, but it gives participants the information necessary for making sound nutritional decisions. Topics on nutrition and health usually include information concerning constituents of diets such as caloric requirements for carbohydrates, proteins and fats as well as information on amount and sources of sodium, potassium, vitamins, and other trace elements. Practical guidelines for food preparation and food purchase also are useful.

Other relevant subjects for a nutrition educational program include behavioral factors. Objectives for diets and eating habits should be explained and specific actions described. The importance of stimulus control, eating habits and social influences should be emphasized. If contracts and incentives are to be used, their rationale and application should be explained thoroughly. Participants and health professionals must be concerned with issues of adherence to recommendations and maintenance of sensible diets and eating habits.

An important part of behavioral management is establishing specific objectives. Objectives should be established by each individual and objectives also should be established for the program. Objectives for individuals should cover food selections that have fewer calories, less fat, less salt, and more essential nutrients. These items should be readily identifiable to facilitate decision making. Vending machine food choices should also include a variety of foods including items low in calories, fat and salt. Many vending operations already offer fresh fruits and low fat or skim milk as alternatives to the higher calorie, higher fat items.

The issue of incentives should be considered when planning a nutrition program. In general, cost-sharing and time-sharing plans that involve use of company time and facilities for lectures, meetings and group activities should be matched by a commitment of time and expense by employees. Tangible rewards may be offered that have dollar value for reaching specific objectives but symbolic rewards that have token value but high visibility also can be good incentives. Prizes, award ceremonies and social events may provide symbolic rewards. The strongest incentives of all are peer approval and supervisor approval. Personal satisfaction in improved appearance following weight reduction also has incentive value.

6. Evaluation: The impact of a nutrition program on coronary heart disease would take several years to evaluate. Fortunately, the effectiveness of a nutrition program can be evaluated using other measures. Comparisons of participants in a nutrition program should be made with control groups that are properly matched or comparisons with baseline measures of the same individuals can be made before and during the program. These outcome measures may include attainment of specific objectives, interest and participation by employees and their families, continuing levels of activity

in the nutrition program, as well as comparisons with other similar groups.

Periodic evaluations provide information on the impact of the program and provide information to participants about the effectiveness of their own individual efforts. Measures to be evaluated include body weight, serum lipid levels, blood pressure, contents of food and activity diaries, problem detection and solution, health care utilization, measures of mood and morale, assessments of activities of daily living, and evaluations of job performance such as absenteeism, accidents, sickness and productivity measures. Analysis of these data should provide a basis for improving the program for each individual and assessing the impact on health, morale and job performance.

D. Program: Stress Management

1. **Background:** A recent poll revealed that 85 percent of Americans feel there is "too much stress in their lives." Although the definition of stress is not yet uniform, the perception of its effect appears to be well understood by the public. It is estimated that stress in the workplace and its effect on performance, absenteeism, alcoholism and disease costs American industry $10 to $20 billion per year.

Recently, a select committee of experts met with key officials of the National Heart, Lung, and Blood Institute to determine the role of coronary-prone behavior in coronary heart disease. The consensus of this group of 50 scientists was that type A behavior, as described by Rosenman and Friedman,[15] was a powerful factor in coronary heart disease and was deserving of equal rank with other risk factors.

There is preliminary evidence that the reduction of stress in industry is associated with: (a) an increased *esprit de corps,* (b) greater productivity (fewer mistakes), (c) a decrease in absenteeism, (d) improved employee/supervisor relations, and (e) a reduction in stress-linked illnesses. It is premature to determine the full impact of such programs and the validity of these preliminary impressions. It is not premature, however, to indicate that the stress management program is frequently viewed as the strongest indication of management concern for employees. Frequently these programs encourage employees to participate in other health promotion efforts offered by the corporation. As such, stress management is frequently considered the centerpiece of health promotion programs, although its formal relationship and established cost effectiveness remain to be defined over the next decade.

2. **Purpose:** To reduce the incidence of stress-linked illnesses in occupational settings through scientifically based stress management techniques and to reduce self-destructive behavioral patterns that may lead to illness and interpersonal job-related and other incompatibilities.

3. **Objective:** The objective is to make available the following types of programs for voluntary participation: (a) Cognitive reorganization (restructuring beliefs and attitudes); (b) assertiveness training; (c) relaxation techniques; (d) time management strategies; (e) modification of undesirable features of type A lifestyle; and (f) environmental restructuring to modify stress-inducing facets of the occupational workplace where possible.

4. **Operational principles for implementation:** It is important that such programs be directed by experienced professional personnel. Individual, group, seminar and clinical consultative experience is important. Involvement of the spouse is very helpful. Frequently, such programs can be moved from the occupational setting and conducted in the evening in order to obtain participation of the life companions of employees. In addition, the program must be in tune with the goals and objectives of the corporation. Management must understand that stress management needs to be oriented in a supportive fashion. At the same time, the perception of the participants must be that this is a program oriented primarily to the personal development of the employee. It is not a means of getting more work out of the employee. Successful implementation thus is based upon a clear mutual perspective between labor and management. In this area, behavioral psychologists may cooperate with the medical director in the program. Caution is recommended in selection of this type of personnel owing to the high sensitivity of the areas encompassed.

5. **Services:**

a. *Cognitive reorganization:* Unrewarding and self-defeating attitudes of individuals are unproductive and frequently self-destructive. Since this behavior is learned, it is optimistic to consider that it can be unlearned and that more suitable behaviors can replace the discarded, more destructive ones. This type of program involves new learning processes and therefore is strongly associated with the learning curve for memory retention. Whatever is accomplished within a period of 6 weeks must be reinforced for a period of time until it becomes incorporated in the individual's behavior. Group seminars are adequate for the majority of people; individual consultation may be required in selected instances. Individual structure will vary widely, depending upon the circumstances and the clinical instructor. Usually these courses are conducted for 2 to 3 hours twice weekly for 6 weeks followed by reinforcement sessions at intervals.

b. *Assertiveness training:* This type of program facilitates decision-making participation in working groups and the expression of thoughts and feelings in a direct nonpejorative fashion. Programs will be designed to examine supervisor-supervisee relationships, co-worker interactions, group participative activities, as well as training in conflict resolution skills and problem-solving strategies.

c. *Relaxation techniques:* Programs can be developed utilizing: (1) progressive muscle relaxation, (2) scientifically based meditative techniques, and (3) biofeedback-assisted relaxation. These techniques encourage employees to become aware of their levels of muscle tone in various situations and to develop countermeasures to the state of chronic physiologic arousal

deemed prodromal to many debilitating disorders (for example, high blood pressure, stroke, heart attack).

d. *Time management:* For many supervisors and managers, job responsibilities expand beyond apparent time available and a high stress situation with concomitant loss of effectiveness can occur when this becomes a chronic condition. This type of program can assist employees in analyzing and reorganizing current time expenditures to obtain maximal impact from this finite resource.

e. *Type A lifestyle modification:* It is important to recognize that approximately 50 percent of the male population in some studies and an increasing number of females demonstrate type A (coronary prone) behavior.[16,17] Some employees may seek assistance in modifying this behavior. Aiding certain employees in evaluating their overall effectiveness while competitive, aggressive and time-urgent offers initial awareness in setting the stage for behavioral change. When awareness has been achieved and recognition of potential health consequences of this behavior determined, the individual may recognize the increasingly ineffectual, self-defeating and perhaps even self-destructive nature of this behavior. Such awareness may provide the motivation to participate in one of the other stress management programs in an attempt to modify facets of this behavior. Individuals can be encouraged to experiment with alternative, less health-detrimental approaches to their work and leisure activities through the programs outlined above.

f. *Environmental modification:* Modification of stress-inducing facets of the workplace is powerful and important in stress management. These stressors range from subsonic vibrations that produce fatigue and irritability and lead to errors and potential injuries, to disruptive scheduling changes related to work shift. These factors can frequently be modified to the advantage of the individual and management alike. Although there have been relatively few studies regarding stress management in the occupational setting, limited research to date has demonstrated reduction in absenteeism and other encouraging results.

Despite absence of hard data, one cannot deny the importance of public reception of this program. It is perhaps the most personally and humanistically oriented of all those offered. Other programs frequently have to do with a "takeaway" approach. This program is oriented toward individual enrichment and can serve to offset some of the "don't do's" of the other programs.

6. Evaluation: Objective evaluation of the impact of an isolated stress management program remains a dream and not a reality. The program interrelates as a catalyst with other programs and, as such, the enthusiasm for the health promotion program in the occupational setting is a reflection of the satisfaction with the stress management program. Inevitably the impact on absenteeism, stress-linked illness and so forth can give a direction but is not a finite indicator of the program. Initially, one can utilize the "happiness index" on the basis of subjective questionnaires at the completion of the stress management program. Several psychological measuring sticks are available at this time. Utilization of such instruments will depend upon the type of program and the program director's background in stress management.

E. Program: Exercise

1. Background: Physical activity programs in occupational settings are increasingly popular as a means to promote the health of some employees. An explanation for their popularity may be that they offer a positive approach to cardiovascular health. Exercise is something participants can do for themselves in addition to what they enjoy already, whereas reducing weight, stopping smoking and taking antihypertensive medication seem, by comparison, to be inhibiting and unattractive. A convenient strategy for introducing health promotion programs may be to initiate an exercise program that incorporates group activities, divisional organization, leadership by volunteers and friendly rivalry among individuals and groups.

Although exercise programs have received a great deal of publicity, their benefits in reducing cardiovascular disease are still uncertain. Scientific evidence from many sources suggests that people who are vigorously active have less heart disease, have an increased sense of well being and are less depressed and anxious than are people who are sedentary.[18,19] If people entering an exercise program also stop smoking cigarettes, alter their diet, lower their body weight, reduce serum lipids and bring levels of arterial blood pressure to ideal values, then they probably lower their risk for cardiovascular disease. At present, it seems most sensible for physicians to advocate physical activity programs in industry as an adjunct to the elimination of cigarette smoking and to the control of blood pressure, serum lipid levels and obesity. The extent of discussion in this section is based upon the committee's consensus that the key issues involving the uncertainty should be presented.

The use of exercise tolerance testing in a physical activity program depends upon the intensity of physical activity to be undertaken and the risk for latent ischemic heart disease in participants. The value of exercise tolerance testing in screening individuals for strenuous exercise programs is not doubted. However, disagreement exists concerning the value of exercise tolerance testing in revealing the presence of latent ischemic heart disease in subjects without major cardiovascular risk factors. In persons under age 35 without manifestations of heart disease and without risk factors for coronary heart disease, exercise tolerance testing is not necessary in screening participants before they undertake vigorous exercise. However, exercise tolerance testing does provide a measure of cardiovascular functional capacity of an individual participant. Individuals over 35 and individuals with major risk factors for coronary heart disease should have exercise tolerance tests before undertaking a sizable increase in physicial activity. The

purpose of such testing during and after maximal or submaximal exercise is to detect electrocardiographic abnormalities indicating that strenuous exercise might precipitate clinical coronary artery disease.

2. Purpose: The purpose of advocating physical activity programs in industrial/occupational settings is possibly to delay or prevent the development of coronary disease. These programs may also serve as adjuncts to elimination of cigarette smoking and to control of blood pressure, serum lipid levels and obesity. They may serve to enhance physical work capacity.

3. Objectives: The objectives of this program are to reduce the incidence and prevalence of cardiovascular disease, increase physical fitness through participation in vigorous recreational activities, improve psychological health, reduce prevalence and severity of cardiovascular risk factors and avoid injury.

4. Operational principles for implementation: The likelihood that an exercise program will be successful and the measure for quantitating its success depend upon thorough evaluation of employees and the occupational setting before the program begins. Demographic characteristics should be determined, health and illness data assembled and summaries of health care service utilization should be prepared. Physical and laboratory data relevant to cardiovascular risk factors and coronary artery disease should be sought. The history of exercise programs and other health promotion programs currently or previously in operation should be reviewed. If possible, the attitudes of decision makers, middle managers and white collar and blue collar employees to exercise programs should be determined. Finally, a survey of community resources is useful to reveal what recreational facilities, physical fitness programs and physical educators are available. Also, the attitudes and knowledge of local physicians and the existence of similar programs in other settings should be determined.

Many avenues are available for establishing program visibility and spreading information. Newsletters, posters, mailers, lectures and demonstrations all can be useful. Specific individuals known to be at high risk for coronary artery disease or individuals of special concern to the organization such as decision makers and managers may be targeted for special effort in recruitment. An ideal opportunity to develop social and environmental situations favorable for exercise programs is the targeting of specific operational divisions for intensive efforts in promotion and recruitment.

A special concern for promotion and recruitment in exercise programs is involvement of other family members, especially spouses of employees. Recreational activities may take time away from the family and other family members may resent the loss of that time. If recreational activities can be shared, resentment may be lessened or avoided.

Persons with signs and symptoms suggestive of coronary artery disease, diabetes mellitus or other major medical illness should be encouraged to consult their personal physician.

An alternative to exercise testing as a preliminary step in obtaining clearance for vigorous exercise is to require a letter of permission to participate in an exercise program from the private physician of the prospective participant. This procedure shifts the burden of responsibility for safety away from the sponsoring corporation but it misses the opportunity to establish a baseline of cardiovascular functional capacity and to evaluate cardiovascular responses to a conditioning program. An intermediate step is to require a letter of permission from a physician for those individuals who are eligible to progress into a more advanced level of exercise.

Individualized exercise recommendations should be prepared whenever there is no contraindication to increased physical activity. The type, intensity, duration and frequency of exercise recommended should be based on the participant's health, estimated physical capabilities, physical activity interests and proficiency, and on the recreational facilities available. Guidelines to warm-up and cool-down periods as well as safeguards should also be specified for each participant.

Special attention should also be given to the manner of reporting results of health risk appraisals to personal physicians. A description of the program and its objectives, results of laboratory data obtained, physical measures made and other information available should be provided to physicians. Copies of reports given to the participants should be sent to their physicians, and a description of the programs available in the corporation sponsoring the health promotion and disease prevention program should be provided. Success of the program ultimately is influenced strongly by the attitudes of the physicians in the community; experience shows that they respond well when they are informed about programs involving their patients.

Many corporations have provided physical fitness facilities and hired physical educators to conduct programs. Community resources should also be utilized whenever possible to broaden the scope of programs by making facilities more accessible to families. Sponsoring programs limited to walking is excessively narrow; every effort should be made to include calisthenics, dancing, bicycling, swimming, racquet sports, as well as team sports such as volleyball, basketball and hockey. Even bowling and golf are a good beginning for sedentary individuals not accustomed to vigorous exercise. Use of community facilities can be monitored by attendance records and evidence of improvement in heart rate response to exercise, in strength and flexibility, body weight and skinfold thickness. As many facilities and professional personnel as possible should be available to all participants. Practical experience shows that if physical fitness facilities are to be used they must be close to work or home, pleasant and safe, and their use should be expedited by the sponsoring corporation on a cost-sharing and time-sharing basis with employees.

Corporations should also supply on-site facilities if at all possible. Showers and lockers for both men and

women are greatly appreciated by employees who walk, run or bicycle to and from work, and recreational facilities such as gymnasiums, running tracks, circuit training rooms, swimming pools and racquet courts are much more expensive than other resources for health promotion and disease prevention programs. Consequently, great care must be taken not to spend all the money available on elaborate facilities just because they are visible and fashionable. The purpose in establishing a physical activity program is to introduce other health promotion and disease prevention programs along with it. Therefore, enough resources must be available to develop a balanced program in addition to fitness and recreational facilities.

Good professional personnel supervising the health programs are even more important than good facilities. Those concerned with physical activity programs must be capable of much more than leading fitness classes and showing participants how to count their pulse rate. They also must be competent in nutrition, psychology and health education. Nurses, physicians, psychologists, dietitians and health educators also should be available as consultants. Employee volunteers are also valuable as leaders and organizers of employee groups. When these people are educated and supervised and their efforts channeled, they are an important source of spirit and enthusiasm for group recreational facilities.

5. Services: The components of a physical activity program include many services in addition to provision of recreational facilities:

a. *Baseline measures and evaluation:* Through these measures it should be possible to determine the health-related costs in a corporation, the epidemiology of health-related behaviors and measures, as well as the prospects for improving health and preventing disease.

b. *Health risk appraisal:* Present health status of employees can be determined and recommendations made to improve health and prevent disease. Detection of signs and symptoms caused by subclinical disease and referral for early care are valuable products of this service.

c. *Facilities:* These must be supervised, inspected, certified and maintained to ensure a high quality physical activity program.

d. *Professional personnel:* These individuals must be recruited, certified, trained and periodically evaluated to maintain a high quality program.

e. *Education:* Attention must be paid to improving attitudes, knowledge and skills of participants in exercise programs. Attention also must be paid to improving attitudes and knowledge of managers, decision makers, other employees and the general public in contact with program participants.

f. *Supervision:* Initial appraisal, individual counseling and periodic evaluation with feedback are essential parts of a physical activity program.

6. Evaluation: The impact of physical activity programs on coronary artery disease would take several years to evaluate. Fortunately, the effectiveness of health programs can be evaluated by using other measures. Comparisons of participants in a program should be made with comparison groups that are properly matched. Alternatively, comparisons with baseline measures of the same individuals can be made before and during the program. These measures may include:

a. *Outcome measures:*
   (1) Incidence of cardiovascular disease.
   (2) Physical fitness, including physical working capacity, body weight and utilization of facilities.
   (3) Psychological health, including psychometric tests, results of interviews and questionnaires and measures of satisfaction with work.
   (4) Cardiovascular risk factor prevalence and severity.
   (5) Participant satisfaction with physical activity programs.

b. *Economic benefits:*
   (1) Production costs, including absenteeism, productivity measures and employee turnover.
   (2) Health costs, including health care service utilization, accidents, medical illiness, insurance costs and insurance rebates.
   (3) Program costs computed on the basis of cost per participant and cost per employee eligible to participate.

c. *Social benefits:*
   (1) Employer-employee relations, including satisfaction with work.
   (2) Public relations including recognition from local government, general public, other corporations and customers.

F. Program: Control of Alcohol Abuse

1. Background: Alcohol abuse is in a different category from the other behaviors addressed in this report. Programs directed toward this problem are in the general realm of *treatment.* (There is of course a potential for progress in industry for the prevention of the occurrence of this problem; this area is dealt with in other reports.)

Unlike the health hazards of smoking, the health hazards of alcohol consumption relate almost entirely to its *excessive* use (either episodically or consistently) rather than its responsible moderate use. In addition to the well known mental and physical effects of alcohol, it is becoming increasingly clear that both hypertension and sudden cardiac death may also be related to its excessive consumption.[20–23] There is, of course, variable susceptibility to alcohol, but in general the threshold for involvement of heart muscle is between 3 and 6 ounces of alcohol/day (2 to 3 ounces of absolute alcohol). Involvement of the heart can occur on a variety of bases. Alcohol may induce abnormal heart rhythms. Alcohol has also been reported to remove components of heart muscle when taken in excess, and it is generally conceded that these are irreplaceable. The result is a loss of heart muscle that weakens the pump and may cause it to fail. In addition, the use of alcohol to excess deadens

the senses and may reduce angina, the signals coming from the heart that lacks oxygen. In this setting, an individual may perform more strenuous physical activity on the basis of the general "anesthesia" and the absence of a life-saving feedback signal.

Beyond the cardiovascular toll there is a well recognized individual and social toll that weighs heavily upon the effectiveness of any worker in industry and that worker's ability to maintain normal relationships in his home and community as well. Obviously, too, alcohol affects many other organs and contributes to a variety of diseases and derangements.[24]

2. Purpose: The purpose of this program is to identify those who utilize alcohol to excess and to control its use. Alcoholic injury to the liver is known to result from three or more alcoholic drinks per day (7 ounces of 86 proof or 3 ounces absolute alcohol).[25,26]

3. Objective: The objective of this program is to combat alcohol abuse through occupational or industrial medicine under the direction of physicians, to assure that no individual consumes more than 2 ounces of absolute alcohol/day if possible and to avoid increasing daily use of alcohol.[27–29] Early detection and rehabilitation are vital. Alcoholic rehabilitation programs should be designed to protect the employee's opportunity for work as long as the individual's work is satisfactory. Such programs utilized to combat alcohol abuse must also include public information on alcohol abuse that can be made available to all employees, their families and, when appropriate, to the community in general.

4. Operational principles for implementation:

a. *The health planning group and especially management and the union,* if present, must strongly and in an unqualified fashion commit themselves to support and implement the plan.

b. *The commitment and principles* must be spelled out specifically in an efficiently adopted statement of policy approved by management, labor and the medical staff.

c. *Funding* should be consistent to provide necessary staffing and operating expenses for the program.

d. *Alcohol abuse should be handled like any other disability* under the disability benefits program. Health and hospitalization insurance coverage might be extended to the same degree as for other medical or surgical diseases or disabilities; it might also include coverage of ambulatory and inpatient care. Currently, such an extension to facilities approved by medical departments is often available at no increase in premium costs.

e. *The program must be confidential* as are all medical matters.

f. *Employees can be referred* by themselves, a union steward, a supervisor or medical personnel as deemed necessary as part of the program.

g. *Supervisors should be given extensive training* in referral to these programs. New supervisory personnel should also be trained as they assume roles.

h. *Referral of workers by their supervisor* may be on the basis of defects in work performance not resolved by usual supervisory techniques. The worker should be told that the possibility of a health matter influencing work is the reason for the referral, not drinking or other reasons.

i. *Skilled professional counselors* should be available in the occupational setting to receive referrals, counsel and coordinate referrals to outside sources for ambulatory or inpatient care.

j. *Services of counselors in the health promotion program* should be made available to spouses or children of the employees upon request. Here the liability risk must be considered.

k. *Policy* should state specifically that involvement in the program will not be a reason for lower standards of work performance.

l. *The employee must be aware that continued failure to meet work standard requirements will require dismissal.* Action should be consistent with that notice after reasonable time has been allowed and opportunities made available for gaining and retaining control of health problems.

5. Services: In this instance, the services provided depend upon the resources of the occupational setting and those of the immediate community for providing alcohol control programs in line with the operational principles described.

6. Evaluation: Ongoing program evaluation includes periodic medical examination, employee work performance ratings by supervisors and absenteeism rates among others.

Task Force 4: The Physician in the Hospital

LOUIS GILLESPIE, Jr., MD, FACC, (CO-CHAIRMAN), JACK H. HALL, MD, FACC, (CO-CHAIRMAN), CHARLES L. CURRY, MD, FACC, SAMUEL M. FOX, III, MD, FACC, J. O'NEAL HUMPHRIES, MD, FACC, RICHARD E. HURLEY, MD, JORGE LITVAK, MD, M. JEANNE PONTIUS, RN, ELLIOT RAPAPORT, MD, FACC, EMILY RICHMAN, RD, ROBERT C. SCHLANT, MD, FACC, H. ROBERT SILVERSTEIN, MD, FACC, SHARON L. YENNEY

I. Introduction

Physicians, dietitians, nurses, hospital administrators and educators of Task Force 4 addressed their roles in the prevention of coronary heart disease in the hospital setting. The title of this Task Force Report indicates the physician's continuing primary responsibility in directing the present and future efforts to prevent coronary heart disease. These efforts must be directed not only at those with identified coronary heart disease and those identified to be at risk for future development of coronary heart disease but also at the entire population. This Task Force recognized early in its deliberations of this important health topic that attention had to be paid to formulating the total health team to provide important assistance to the physician so that the team effort necessary to provide the optimal educational impact can be accomplished. Therefore, this Task Force addressed the roles of all health professionals available in the hospital with regard to prevention of coronary heart disease.

The significance of the hospital as an industry and as a resource in the community was also considered. During the past 2 decades, the combined pressures of rapidly advancing technology and cost containment in the United States have forced hospitals to direct their resources increasingly to acute in-patient care. Hospital stays are becoming more and more complicated and briefer. A hospital stay is a confusing and emotionally stressful time for patients and their families. Under these conditions, where does prevention fit in and how could it become a more integral part of hospital services?

We recognize that prevention in the patient with clinical coronary heart disease encompasses far more than efforts directed toward risk factor modification. However, for the purpose of this document we shall be concerned with approaches toward lifestyle modification that can be universally applied to virtually all patients in the hospital setting as well as to the general community.

II. The Hospital's Role in Preventive Education

Although risk factor assessment, education and control should usually be instigated outside the hospital setting, the period of hospitalization is one in which the

potential impact of education is great and offers a unique opportunity for reinforcement. A patient's response to preventive education depends on three factors: (1) effective communication of the message, (2) the patient's intelligence, and (3) the patient's motivation. Patient motivation is significantly affected by changes in health status and, specifically, by hospitalization. Educational messages should also have an impact on asymptomatic ambulatory patients. However, this impact requires greater and continuing reinforcement, but ambulatory patients may be less anxious and confused than their hospitalized counterparts and therefore more receptive.

A. Cardiovascular Patients

Upon hospitalization, an individual's health becomes a central concern. The events that lead to hospitalization and the hospitalization period itself may be dramatic and frightening to the cardiovascular patient. The patient may have experienced episodes of angina pectoris or an acute myocardial infarction. In almost every instance, the hospitalized patient suddenly experiences heightened motivation to learn about risk factors and their prevention. In addition, the patient and family members are more available and likely to pay attention to the health education message.

In many hospitals, that have significant programs directed toward the diagnosis and treatment of coronary artery disease, preventive educational programs exist as well, but these programs are often haphazard and informally developed stepchildren to the diagnostic and surgical procedures. Physicians often do—but should not—limit their communications to the facts surrounding diagnosis and treatment. In institutions where cardiac patients, medical or surgical, are placed in designated nursing units, the circumstances for initiating educational programs are particularly favorable. The nursing staff often develops *instructional programs* for their convalescing patients. However, these educational activities commonly remain isolated, and the efforts cease at the time of discharge. There should be improved coordination of these efforts among nursing staff, physicians, and other professionals who might carry these activities into the postdischarge period.

B. Noncardiovascular Patients

The unmet potential for preventive education in the hospital setting is *not limited to the cardiovascular patient*. The hospital could provide all appropriate patients with important information on their coronary health status based on routinely performed tests. These results could be correlated with self-administered questionnaires or staff interviews on admission concerning the subjective and objective data relating to coronary heart disease (for example, tobacco use, blood pressure, lipid levels, weight). Such information developed in the patient's chart then becomes available for the attending physician's review and subsequent recommendation of an educational program during the stay in hospital or thereafter.

Before or at hospital discharge a specific *plan for follow-up* should be approved by the attending physician with notation as to what has been done and how further efforts will be pursued. Only the patient who has been well informed by health professionals in the hospital is properly equipped to assume responsibility for any necessary changes in lifestyle and preventive therapy (for hypertension, for example).

C. Linkages Between Inpatient and Outpatient Programs

Although many hospitals are involved in community health education, appropriate *linkages between inpatient and outpatient programs* have not been delineated. A continuous preventive program should be developed by physicians in collaboration with nurses, dietitians or other health professionals. *The following steps should be taken to develop or enhance existing ambulatory programs* in local communities to carry out continuing activities to reduce coronary artery disease and atherosclerotic disease in general:

1. *Standardized program guidelines* should be developed by a national joint committee of representatives of the various professional organizations concerned with prevention of coronary heart disease. These guidelines should be prudent and based upon established scientific facts utilizing, wherever possible, information from already established programs. The program guidelines should ultimately contain information on the risk factors related to coronary heart disease and on measures to alter or control lifestyle, including dietary and smoking instruction, exercise information and supervision (if an exercise facility is available) and information on control of high blood pressure.
2. *Local courses and counseling services,* based on the above standardized program guidelines, should be established or expanded.
3. *The means for continued financial support* should be assured from the outset to ensure the longevity and quality of the program.
4. *When such a program has been established, physicians should be encouraged to recommend participation* to their patients with cardiovascular problems, whether established or potential. This ambulatory program should be recommended either at the time of hospital discharge or at the time of identification of cardiovascular risk factors. Further outreach to the entire populace, or to specific segments—for example, school populations and members of civic organizations and labor forces—should be a continuing consideration by the educational program.
5. *The hospital should share sponsorship* of such education programs with its medical staff and other institutional health professionals.
6. *The hospital should supply resources*—both physical and public information—to support the growth and strength of this educational program.

III. The Hospital As an Employer

The hospital should be a model as an employer interested in the health and well-being of its employees. It should *provide programs* that survey, inform, guide and encourage the development of *positive health habits.*

The hospital should provide an assessment of health risks for all employees beyond the immediate demand for care of acute disability and worker compensation. There should be a nutrition service that provides education and food service consistent with the prudent diet to reduce risks of coronary heart disease. There should be programs to inform and aid in the control of weight and cigarette smoking. Each employee should be informed of his or her own blood pressure, serum cholesterol, weight and the adverse effects of cigarette smoking.

There should be employee health programs related to lifestyles and coronary risk factors. This exemplary role may take many forms—the regular provision of health awareness campaigns; establishing good health practices within the hospital facility such as enacting stringent smoking regulations for patients, staff and visitors; carefully noting on all menus for patients or visitors the nutritional content of the food served and identifying those selections that are particularly healthful; providing exercise and fitness programs. The health care forces in the hospital should cooperate to teach patients, employees and visitors that good health is a personal responsibility and each should know his or her status related to the risk factors of his or her age and sex.

IV. The Hospital As a Resource

The hospital and its staff should be a community resource in blood pressure screening, programming for cigarette smoking cessation, blood lipid screening, weight control, diagnosis and management of diabetes mellitus, exercise activity and cardiopulmonary resuscitation. In addition, hospitals have several unique opportunities to take a leadership role in education for prevention of coronary heart disease. They can provide a facility for activities such as community education, patient education, physical fitness classes, self-help and support groups and risk-screening programs. The community usually views its hospitals as institutions that are capable of organizing and activating other agencies in the local area. In addition to providing physical space for prevention services, hospitals frequently have ongoing working relationships with other agencies and institutions in the community and can draw upon their help to supplement the resources, including funding, needed for prevention activities.

Hospitals can influence the education of professionals who are obtaining their clinical experience in hospitals. The curriculum for medical, nursing, laboratory and other technical personnel should include a significant exposure to preventive cardiology. Staff education as well as continuing education conducted by the hospital for its employees should also emphasize preventive and rehabilitative services.

V. Health Professional Roles in Preventive Education

The hospital may be viewed as bricks, mortar and sophisticated equipment, but it is the various professionals within that physical structure who must work together to produce a program that successfully accomplishes the goals set forth by this Bethesda Conference. Four specific groups, present in all hospitals, were discussed by the Task Force: physicians, nurses, dietitians and hospital administrators.

A. Physicians

The advocacy role of physicians regarding behavioral change for the prevention of coronary heart disease cannot be overemphasized. Studies have shown that the physician is the person most likely to influence patient behavior in regard to health. If we are to improve preventive medical care in this country, we must convince physicians of the value of the preventive approach so that they will convince their patients.

In the hospital setting the leadership of the medical staff should encourage the continuing education of their colleagues in coronary risk prevention. Physicians should participate in committee and teaching functions for education of coronary risk prevention.

The medical staff must appreciate the need to utilize nursing, dietary and other professional support in developing strong coronary prevention programs. Physicians should assure that all patients are informed of all risk factors.

B. Nurses

Because of sustained contact with patients, nurses are in an ideal position to reinforce the patients' understanding of risk factors, to present portions of the educational program and to assist in preparing patients to assume the necessary responsibility for their own behavior. The role of the nurse is particularly significant in the early planning for discharge. Many nursing educational programs now prepare nurses for their important role in the prevention of coronary heart disease. However, nurses generally need to be encouraged to accept this involvement, by staff development programs and recognition of their responsibility.

C. Dietitians

Because the risk factors for coronary heart disease are significantly related to various aspects of nutrient intake, the dietitian should be actively involved in the health care team. This involvement should include assessment of the nutritional well-being of the patient and assistance in the practical application of physicians' diet prescriptions for patients and their families. Such dietary consultations should be available to hospitalized and ambulatory patients, as well as to participants in ambulatory programs to decrease the risk of coronary heart disease in asymptomatic individuals.

The dietitian should assure that the food service provides all hospitalized patients with a diet that is attractive and palatable and that reflects nutritional recommendations appropriate for risk reduction of coronary heart disease, that is, reduced calories from total fat, particularly saturated fat, decreased cholesterol, decreased sodium and reduced caloric intake where appropriate. Concurrently, this diet should emphasize the intake of foods that are high in complex carbohydrates, vitamins and minerals in relation to other nutrients. Although the brief period of hospital-

ization for most patients cannot be expected to lead to a long-term change in eating habits, it can provide a beginning for continuing education about dietary modification.

The dietitian should ensure that employee food service facilities in the hospital include diets that meet accepted recommendations to reduce risk of coronary heart disease.

D. Hospital Administrators

Hospital administrators should seek opportunities to implement effective programs for the prevention of coronary heart disease. After assessing the needs of their specific communities, administrators should determine the most appropriate method of fulfilling those needs, as an important objective of the hospital. Administrators should provide appropriate risk factor identification and education programs for all hospital employees and should adopt hospital policies and procedures that are in concert with known, effective preventive techniques such as prohibiting the sale of smoking materials and of smoking, except in designated areas, and providing food services that support nutritional standards. Wherever possible, hospital facilities, staff and teaching resources should be made available for prevention programs. Administration should actively seek funding sources to support prevention activities.

VI. Recommendations

A. *The physician in the hospital setting* has the responsibility to initiate and direct appropriate efforts to prevent coronary heart disease in both in- and outpatients, as well as the institutional staff and employees. Optimal discharge of this responsibility requires a team effort; key members of the team include nurses, dietitians and hospital administrators.

B. *Hospitalized patients should be given the information in the medical record* about their weight, blood pressure, blood sugar, serum cholesterol and other factors. Preventive recommendations by the attending physicians should be included in the discharge summary. Educational efforts provided by physicians, nurses, dietitians or other health professionals should be noted in the medical record.

C. *The hospital should offer a coronary risk assessment program* available to both in- and outpatients upon request of their physicians.

D. *The hospital should provide a program for its employees and staff* for risk factor assessment, including blood pressure, smoking pattern, serum cholesterol, body weight, diabetes mellitus, nutrition and physical activity. Health programs should be available to help employees and staff modify lifestyles and risk factors.

E. *The hospital should serve as a learning center that encourages coronary prevention in the curriculum of all students affiliated with it.* It should provide a health education program under the supervision of the medical, nursing and dietary staff for employees, patients and members of the community.

F. *Standardized educational program guidelines should be developed* based on prudent judgment and established scientific facts from which local ambulatory programs can be developed or existing programs enhanced. These programs, if sponsored by the hospital, should be under the supervision of health care professionals associated with the hospital. The hospital should look to its medical staff to provide guidance in these programs.

G. *A prudent diet should be available* and physicians should, when appropriate, encourage its use. This diet should be clearly identified for selection by hospitalized patients, employees and staff.

Task Force 5: The Preparation of Future Medical Practitioners (Medical Education at the Undergraduate, Graduate and Postgraduate Level)

NEMAT O. BORHANI, MD, FACC, (CHAIRMAN), ROBERT L. BERAN, PhD,
HENRY W. BLACKBURN, Jr., MD, FACC, THOMAS A. BRUCE, MD, FACC,

RICHARD JONES, MD, NORMAN M. KAPLAN, MD, DAN G. McNAMARA, MD, FACC,
BARBARA PACKARD, PhD, MD, NORMAN S. STEARNS, MD, WILLIAM B. STRONG, MD, FACC

I. Introduction

The primary focus of the Task Force Report is the development of a meaningful and effective educational program for coronary prevention, with emphasis upon a curriculum that encompasses and integrates the education of medical students, house staff and practicing physicians. One cannot underestimate the importance and the problem of developing and implementing a curriculum on cardiovascular disease prevention. The report of this Task Force is designed to be of help to all who wish to advance this critical area.

Because of the continuing large incidence of coronary heart disease, the potential for prevention of premature morbidity and mortality is great. To realize this po-

TABLE I

* Evaluation involves all parts during—not after—development.

tential, medical students, house staff and practicing physicians should become familiar with the basic principles of epidemiology and the primary prevention of coronary heart disease.

Because many interventions for reversing risk factors, for primary and secondary prevention have at times been implemented before they have been definitely proved to be effective, each intervention should be categorized as unclear, possible, likely or of proved scientific benefit. For certain intervention approaches, reasonable differences of judgment may exist as to efficacy. Thus, an effective teaching program must consider this matter.

Significant reduction in coronary heart disease mortality has occurred during the last decade. However, data are limited and inconsistent as to whether a decline has occurred in the incidence of this disease, and in any case millions of people continue to be at risk for premature mortality and morbidity resulting from this malady. This stimulates a desire to broaden and improve our attempts to reduce these risks. For various reasons, a person highly effective in working with individual patients—the primary care physician—is often not formally involved in this effort.

To date, physicians have received little focused information in medical school about preventive cardiology. Epidemiologic, clinical and laboratory investigators have identified risk factors for coronary heart disease. The public and individual patients must be informed about them in a convincing manner. The busy days of practicing physicians are already filled with the needs of patients with acute problems, leaving little or no time properly to explain risk factors and to motivate individual patients to change their lifestyle. However, recent surveys indicate that people think they will be more inclined to alter their lifestyle on the recommendations of their physicians than on recommendations from any other source. For this reason practicing physicians must be trained to provide the latest information on risk factor control to their patients. Physicians must be encouraged to assume responsibility to make the information known to their patients and to monitor their adherence to the advice given.

The purpose of this Task Force on Preparation of Future Medical Practitioners for the prevention of coronary heart disease is to present specific plans to accomplish this on a large scale basis with the most efficient use of physicians' effort and time at the lowest cost.

Four issues are addressed by this Task Force. These are: (1) To design programs to teach prevention of coronary artery disease in such a way that the principles will become incorporated into the routine practice of medicine. (2) To assure that continuing medical education programs provide the most current information to the practitioner that will enable him to pass this on to his patients. (3) To develop a system of evaluation that will allow valid assessment of preventive measures in the management of patients from infancy through late adult life. (4) To develop strategies that will stimulate educational institutions, professional organizations and funding agencies to promote scientific concepts in research and other efforts in primary prevention.

The specific knowledge and skills that the practicing physician, the house staff and the medical student should each have in order to provide direct patient care, or to participate in relevant patient education programs are outlined.

II. A Plan for Program Development

Educational objectives of teaching programs for medical students, house staff and practicing physicians, developed by faculties in schools of medicine, are best accomplished by following an orderly structure of curriculum development, implementation, and evaluation. A useful approach is outlined in Table I. This table outlines a general approach to curricular development, relates this to the development of a program in prevention of coronary heart disease and provides a content outline for this development. Classically, the initial step is a needs assessment that identifies the skills, knowl-

edge and attitudes that should be required of physicians to perform their task in an optimal manner. The needs assessment is indispensable and is usually best accomplished when a group of experts with scientific knowledge and practical experience agree on the optimal behavior goals.

The next step is to define in clear and relatively specific terms the content of a training program that will yield the desired behaviors. The development of this content outline may be refined in a succeeding step by a statement of learning objectives that specify the desired behavior (see *Appendix 1*).

Several aspects of the content outline deserve comment. The outline is intended to be comprehensive and assumes that the entry level is that of a 1st year medical student. No previous knowledge of epidemiology is assumed; this content outline may be used to teach the principles of epidemiology. However, the content outline is not designed to be slavishly followed. Rather, it is intended as a guide or checklist. Moreover, it can be used to design postgraduate education programs as well.

On completion of a content outline (or specific learning objectives), specific curriculum approaches can be defined and developed. These approaches can and usually do encompass a variety of teaching modalities. In development of a specific curricular approach, it is important to match the teaching modality to the learning need. Conventional lectures, syllabus study and audiovisual programs can be developed for information transfer, but the learning of most skills requires actual interactions with case material. A variety of approaches is often required, and care should be taken to match the required behavioral change with an appropriate learning modality. Examples of programs that integrate different approaches include Advanced Cardiac Life Support, Preventive Cardiology Academic Awards and Summer Epidemiology Seminars. In the Advanced Cardiac Life Support program, a syllabus, lectures, problem-solving exercises, identification of arrhythmias and psychomotor skills in intubation and resuscitation comprise the teaching approaches.

An important and often neglected step in program development is evaluation, which includes learner assessment as well as program assessment; evaluation is discussed in section III of this report.

In undergraduate medical education, many topics in the outline are already covered in some schools. The intention is not to rearrange scheduled lectures or replace one topic with another. Rather, the content outline represents a checklist that can be used by faculty and curriculum committees for their integration of curricular coverage. In this manner, faculty can define and correct current deficiencies and ensure reinforcement of the concept throughout the curriculum. For example, many basic aspects of lipoprotein and lipid metabolism are presented in biochemistry. Nevertheless, the synthesis between biochemical aspects and clinical features, such as diet, exercise, diabetes and alcohol consumption, may not receive attention; this synthesis must be presented to the students, so that they see preventive cardiology as an integral part of patient care. Many other areas currently receive little attention and their inclusion in the outline should serve as a reminder of their importance. For example, patient adherence to modification of life patterns is fundamental in improving general health and is critically important in prevention of coronary heart disease. This topic is not usually specifically covered, and its importance is not widely appreciated in medical student training. The use of this content outline may influence curriculum designers to include training in these skills in the curriculum. Although the participants in this Task Force recognize that each medical school faculty is responsible for its own curriculum, it is hoped that the outline provided in this report will serve as a stimulus to reexamine and improve each school's efforts in preventive cardiology.

Although the content outline has been developed primarily for medical students, it can be used to define teaching programs for house staff and for continuing medical education. The requisite knowledge and skills are the same for all student groups. The process may change depending on differing practice situations, but the principles and the educational goals are not different, because the best patient care is the final goal.

III. Evaluation

First, the individual student must be evaluated in terms of his or her learning experience. This requires specification of performance criteria and development of appropriate means to measure performance against these criteria. Testing does not always call for the display or recitation of knowledge, but may include skills performance. The criteria used and their means of measurement are usually dictated by the content outline. Measurement of skills performance poses special challenges, but carefully written learning objectives will specify the acceptable level of performance.

Second, it is important also to evaluate the educational program itself. This usually is carried out in two stages. During program development or implementation, those conducting the program need to carry out a formative evaluation including acceptance by the learners, measured achievement of performance criteria and problems in sequencing. On the basis of this assessment, the program can be altered and improvements made.

Finally, it is important to assess the overall success of the program in altering patient behavior. For a good educational program for health providers, it is important not only to measure gains in knowledge and skills, but also to attempt to change actual practice of physicians and daily activities of the patients. While it is difficult to assess this final—and most important—behavioral measure, there is value in making this evaluation, even if on a limited basis.

To evaluate effectiveness in the achievement of the goals and objectives of the total preventive education

program, methods must be developed to assess the following points:

A. *Acquisition of the content and skills* stipulated in the curriculum related to learning activities (for example, objective and subjective examinations).

B. *Degree (quantity) of use of the developed education and learning materials* in preclinical, clinical and graduate programs (for example, periodic survey).

C. *Changes in personal habits and behavior of the teaching faculty* regarding prevention and risk factor modifications that are effected by the introduction or participation in the institution's prevention education program, or both (for example, pre and post surveys).

D. *Changes in the personal habits and behavior of medical students* as a result of program initiation. An assessment of students' assumption of responsibility for their own risk factors (periodic survey) and recognition of their future role status.

E. *Degree (quantity and quality) of institutional participation in setting an example of proper behavior,* that is, changes in food service, publicity regarding the benefits of exercise, encouraging reduced salt intake and cessation of smoking (periodic survey and interview).

F. *Changes in hospital or clinic medical practice* based on audit of risk factor assessment and intervention in the care of either well "patients" or those with overt manifestations of coronary heart disease.

G. *Systematic collection of information on and student evaluation of the teaching program.*

The evaluation of the education program's success can be undertaken through content examinations, surveys and interviews. Since the success of the program, in many respects, involves desired behavioral changes, the frequent gathering and evaluation of information is imperative. Overall program effectiveness, particularly in the area of initiating changes in institutional attitudes, requires regular and relevant reporting of data. It is most important to evaluate both the content and substance of the educational program and the actual changes.

IV. Strategies for the Most Effective Development of Preventive Cardiology Education

Medical schools and other educational institutions may be reluctant to develop courses or clinical training programs limited to one disease and, more specifically, to the prevention of that one disease. This outline defines potential mechanisms whereby educators may increase their emphasis on teaching the general field of preventive medicine, and coordinate and integrate that teaching effort so that it will be more effective in changing the knowledge, skills and attitudes of students and physicians. It is our belief that the primary prevention of coronary artery disease is one of the best, most appropriate and most relevant models for learning such principles of preventive care.

A. Strategies for gaining nationwide attention and credibility:

1. Encourage medical professional organizations to use primary prevention as a theme for future meetings.
2. Invite philanthropic organizations with a known interest in health care and medical education to place high priority upon innovative demonstration projects on prevention.
3. Increase the coverage of preventive medicine in examinations by the National Board of Medical Examiners and specialty Boards.
4. Encourage medical specialty societies to support health education programs in a visible and substantive way.
5. Provide editorials in appropriate journals about the need for improved educational preparation for physicians in primary prevention as well as the need for further research.
6. Encourage those who sponsor continuing medical education programs to increase the coverage of primary prevention in their curricula.
7. Encourage expanding participation in the Preventive Cardiology Academic Awards Program with extensive publicity about the awards given and the results achieved.

B. Strategies for encouraging medical schools to develop programs in preventive cardiology:

1. Institutional officers should receive information on how preventive programs might be appropriately included in cost reimbursement formulae for Medicare/Medicaid and other categorical insurance programs.
2. Medical schools should encourage their faculty to consider applying for academic awards in preventive cardiology.
3. Medical schools should provide brief "case studies" of successful teaching programs in primary prevention. The packages should be distributed broadly to medical school deans, curriculum committees and heads of divisions of cardiology, preventive medicine, epidemiology and self-study accreditation review groups.
4. Granting agencies should develop small grants for the support of innovative approaches to teaching the prevention of coronary heart disease and provide enough of these so that most acceptable applications will be funded. The availability of these grants should be widely announced.
5. Specialty organizations should include in their annual scientific sessions programs related to the need for better training of physicians in the prevention of coronary heart disease.

C. Strategies and specific examples for implementation of a preventive cardiology curriculum:

1. *A recommended content of a preventive cardiology curriculum* is identified in Appendix 1 of this Task Force report. The strategies by which this material can be incorporated and implemented are presented here. Although the content may be similar, the activities at the medical student, house staff and practicing physician levels differ significantly, and variations in approach will be needed to effect learning. The final

common pathway is a change in physician behavior that allows devotion of thought and time to the practice of preventive techniques, both for the individual high risk patient and the community as a whole.

2. *General principles about implementation include:*

a. The ideal time to educate students about prevention is early, prior to their becoming too heavily oriented toward disease and curative medicine. Time during orientation may be used for assessing individual student's personal risks. These data could be used to teach principles of epidemiology. Since the data are the student's own, they should be more meaningful, thereby enhancing student involvement.

b. Techniques beyond didactic presentations should be used, with active participation of the students, such as participation in community screening programs.

c. The preventive cardiology curriculum should be extended throughout the 4 years rather than being given as a single block. For the student with a particular interest, special preventive cardiology electives should be offered. Students should be involved in the planning of such electives.

d. Prevention should be emphasized in the clinical setting during the students' rotation in obstetrics, pediatrics, internal medicine and family practice services. The student taking care of a patient with an acute myocardial infarction should be responsible for discussing the preventability of the disease as well as planning the patient's rehabilitation program.

e. As in all activities, the faculty should serve as role models.

f. Exercise should be encouraged by having a physical activities center on campus.

g. Demonstration about effective community prevention programs should be presented at each level.

3. *Specific examples:*

a. Medical students
   (1) Introduce prevention concepts early in year 1.
   (2) Determine the student's risk profile.
   (3) Provide correlation conferences using coronary heart disease patients.
   (4) Integrate preventive medicine to the basic science curriculum (for example, given this problem, how could it have been prevented?).
   (5) Provide a separate course in epidemiology and preventive medicine.
   (6) Include risk assessment in the Introduction to Disease course.
   (7) Emphasize prevention during clinical rotations.
      (a) Clinical conferences.
      (b) Study of families of patients.
      (c) Risk assessment and management in both hospital and clinic patients.
   (8) Provide models for prevention in the medical school environment.
      (a) Smoking cessation.
      (b) Nutrition modification by involving hospital food services and school cafeteria.
      (c) Campus exercise program.
   (9) Develop preventive cardiology electives.
   (10) Encourage participation in community preventive programs.

b. House staff.
   (1) Incorporate prevention into hospital in-patient experience.
      (a) Routine risk assessment in every admission workup.
      (b) Clinical conferences.
      (c) Consultation service.
      (d) Patient rounds with nutritionists, health educators, etc.
      (e) Medical audit of current performance.
   (2) Incorporate prevention into outpatient clinic experience.
      (a) Routine risk assessment.
      (b) Use of nutritionists, health educators, etc.
      (c) Home health services.
      (d) Medical audit.
   (3) Provide models within hospital setting (hospital smoking policy, for example).
   (4) Provide teaching programs.
      (a) Formal lectures.
      (b) Analysis of current literature on statistics, epidemiology and preventive medicine.
   (5) Increase coverage of prevention in board examinations.

c. Practicing physicians (continuous medical education)
   (1) Increase coverage of prevention in formal courses, lectures, rounds, clinic-pathologic conferences, etc.
   (2) Perform audits of inpatient and office practice with emphasis on prevention.
   (3) Increase coverage of prevention in certification examinations.
   (4) Encourage use of risk assessments and patient education in practice.
   (5) Encourage involvement of physicians in risk factor management programs.
   (6) Increase coverage of prevention in national meetings, journals.

APPENDIX I

Content Outline for Curriculum on Prevention of Coronary Heart Disease

I. Evidence for Association and Rationale for Intervention

A. *Epidemiologic evidence on risk.*
   Nature of epidemiologic process and nature of

intervention studies.
Evidence from clinical, pathologic and animal-experimental research.

B. *Inferences for prevention.*
Approach for health providers based on current knowledge.
Potential value of prevention (lives saved vs. sudden death, income maintained, cost savings to health system, etc.).

C. *Identification of specific risk factors.*
Those alterable vs. those unalterable:
Blood pressure.
Serum lipids.
Cigarette smoking.
Personality types and psychological factors.
Diabetes mellitus and other metabolic disorders.
Use of estrogens in menopause and birth control.
Body weight (adiposity).
Unalterable, but important factors:
Age.
Sex.
Race.
Unspecified genetic aspects.
Factors lacking strong and consistent evidence:
Socio-economic factors.
Stress (as differentiated from personality).
Exercise.

I. Checklist of Key Risk Factors Amenable to Intervention

A. *Blood pressure.*
1. Appropriate levels for intervention.
2. Confirmation of persistent blood pressure elevation.
3. Special problems:
   a. Variable blood pressure.
   b. Children and adolescents.
   c. Elderly with isolated systolic hypertension.
   d. Interaction of blood pressure with other risk factors.
4. Nonpharmacologic therapy:
   a. Weight reduction.
   b. Dietary salt reduction.
   c. Correction of excess alcohol use.
   d. Combination with drugs or alone.
   e. Impediments to success.
5. Pharmacologic therapy:
   a. Setting goals.
   b. Diuretics.
   c. Adrenergic blocking agents.
   d. Vasodilators.
   e. Combination of agents.
   f. Side effects

B. *Serum lipids.*
Roles of low density lipoproteins, very low density lipoproteins and high density lipoproteins.
Problems of measurement and advice as to which measurements (cholesterol, triglycerides, high density lipoprotein).
Dietary approach.
Pharmacologic approach.
Combinations of drugs and diets.
Expectations of therapy.
Special considerations:
Value after symptomatic disease (angina, myocardial infarction, etc.).
Diabetes mellitus.
Fad diets (macrobiotic, "drinking man's," etc.).

C. *Cigarette smoking.*
Which constituents are harmful and what are potential mechanisms?
Threshold level or critical age?
Interaction with other variables
(blood pressure, cholesterol, oral contraceptives, alcohol, body weight).
Problems of stopping.
Therapeutic approaches:
Group therapy.
Role of physician, other support personnel.
Recidivism, strategies to combat measurement of abstinence.

D. *Weight reduction.*
Role in relation to other risk factors (blood pressure, lipids, glycemia, etc.).
Individual vs. group therapy.
Type of diet.
Special problems (eating out, alcohol, smoking).

E. *Exercise.*
Who should have functional testing, stress electrocardiogram?
Type of exercise prescription.
Orthopedic problems and safety.
Expectations of change.

F. *Other therapies.*
Antiplatelet agents.
Antiarrhythmic agents.
Oral contraception cessation.
Stress control/personality alteration.
Factors affecting endothelium.

III. Specific Approaches to Primary Prevention

A. *Screening.*
Who?
When?
How often?
By whom?
What tests?
Use of work site or community resources.
Follow-up for confirmation.

B. *Decision to initiate therapy.*
   Special considerations:
   Genetic background.
   Risk factor profile.
   Age.
   Sex.
   Race.
   Previous cardiovascular disease.
   Associated diseases.

C. *Family and pediatric aspects.*
   1. General approaches for overall disease prevention, health maintenance, health promotion.
   2. Familial clustering of disease because of shared genes and environment:
      Use of patient with premature arteriosclerosis as indicator for families and children at risk.
      Importance of family intervention with respect to diet, smoking, exercise, blood pressure.
      Availability of normative data for children and adolescents with respect to lipids and blood pressure.
         Sex-related changes at adolescence.
         Concept of "tracking" of blood pressure, and weight and use in screening and follow-up.
         Racial differences in risk factors.
         Concept of arteriosclerosis as a disease beginning in childhood.
   3. Genetic aspects of risk factors and coronary heart disease.
      Monogenetic vs. polygenetic and the interaction with environmental factors.
      Specific patterns of inheritance for hyperlipoproteinemia.
      Genetic aspects of high blood pressure.
         Probably multifactorial disease with polygenetic inheritance and strong environmental influence.
         "Salt-sensitive" concept and data from primitive populations.
         Relationship to obesity and body mass.
         Racial differences as a possible mainfestation of genetic selection, as a possible manifestation of environmental differences
      Genetic aspects of other risk factors.
         Vascular endothelium and mesothelial reaction.
         Platelet aggregability.
         Physical activity.
         Cigarette smoking.
         Obesity.
         Diabetes mellitus.
         Rare genetic diseases associated with premature arteriosclerosis (for example progeria, homocystinuria).
   4. The *process* of using the family for case finding and intervention.
      Specific counseling techniques.
      What age children to screen, frequency of screening.
      Hygienic advice to families regarding diet, activity.
      When to intervene in children using drugs:
         Type IIa children.
         Hypertension.

D. *Changing behavior.*
   Knowledge, skills, attitudes as essentials in education.
   Principles of effective behavior modification.
      Relevant.
      Goal setting.
      Reinforcement.
   Adherence.
      Impediments.
      Monitoring.
      Handling problems.
   Individual instruction.
      How managed.
   Group instruction.
      Favorable situations.
      Size of groups.
      Constructive management.
      Peer support systems.
   Use of media.
      Suggested educational materials.
   Teaching skills to patients.
   Reinforcement techniques.
   Importance of follow-up.
   Frequency of follow-up.
   Common problems of interrelationships.

IV. Secondary Prevention

Although this report has dealt with primary prevention, the concept of secondary prevention (that is, prevention of mortality or morbidity, or both) after development of manifest coronary heart disease (acute myocardial infarction, for example) is important for the following reasons:

A. *Risk factors for second episodes* differing from those for the first, for example, "conventional" risk factors vs. arrhythmias.

B. *Risk status of those with stable angina, unstable angina, or resuscitation following arrhythmic death.*

C. *Intervention on conventional risk factors.*
   Cigarette smoking.
   Obesity.
   High blood pressure.
   Serum cholesterol.
      Diet vs. pharmacologic agents.

Potential effect of cholesterol lowering for secondary prevention.
Behavior pattern.

D. *Intervention for secondary prevention.*
Antiarrhythmic agents.
Antiplatelet agents.
Anticoagulant agents.
Beta blocking agents.

I. The Process of Intervention

A. *Commitment by health providers.*

B. *Setting up a system.*
Public action/public health approach.
Individual/group screening.
The role of physicians.
The role of other health providers.

C. *The sequence of individual assessment.*
Screening.
Confirmation.
Intervention plan/setting goals.
Education.
Knowledge.
Skills.
Attitudes.

D. *Impediments to success.*
Lack of commitment by providers or patients.
No follow-up.
No setting of realistic goals.

elemental potassium (as potassium gluconate, 4.68 g) with saccharin and aromatics. Alcohol 5%.

Indications: Kaon Elixir is indicated for the treatment of potassium depletion in patients with hypokalemia, for the treatment of digitalis intoxication, and for the prevention of potassium depletion when the dietary intake of potassium is inadequate. Prophylactic administration may be indicated in patients receiving digitalis and diuretics for the treatment of congestive heart failure; hepatic cirrhosis with ascites; patients with hypertension on long-term diuretic therapy; patients on corticosteroid therapy; hyperaldosteronism states with normal renal function; the nephrotic syndrome; and certain diarrheal states.

Contraindications: Potassium supplements are contraindicated in patients with hyperkalemia. Hyperkalemia may complicate any of the following conditions: Chronic renal failure, systemic acidosis such as diabetic acidosis, acute dehydration, extensive tissue breakdown as in severe burns, adrenal insufficiency, or the administration of a potassium-sparing diuretic (e.g. spironolactone, triamterene).

Warnings: Do not administer full strength. Kaon Elixir may cause gastrointestinal irritation if administered undiluted. In patients with impaired mechanisms for excreting potassium, the administration of potassium salts can produce hyperkalemia and cardiac arrest. Potentially fatal hyperkalemia can develop rapidly and be asymptomatic. The use of potassium salts in any condition which impairs potassium excretion requires particularly careful monitoring of the serum potassium concentration and appropriate dosage adjustment.

Hypokalemia should not be treated by the concomitant administration of potassium salts and a potassium-sparing diuretic (e.g. spironolactone or triamterene).

Precautions: The diagnosis of potassium depletion is ordinarily made by demonstrating hypokalemia in a patient with a clinical history suggesting some cause for potassium depletion. In interpreting the serum potassium level, acute alkalosis per se can produce hypokalemia in the absence of a deficit in total body potassium, while acute acidosis per se can increase the serum potassium concentration into the normal range even in the presence of a reduced total body potassium. The treatment of potassium depletion, particularly in the presence of cardiac disease, renal disease, or acidosis, requires careful attention to acid-base balance and appropriate monitoring of serum electrolytes, the electrocardiogram, and the clinical status of the patient. In hypokalemic states, hypochloremic alkalosis is a possibility that may require chloride as well as potassium supplementation. In these circumstances, potassium replacement with potassium chloride (e.g. Kaochlor 10% Liquid, W-T) may be more advantageous than with other potassium salts.

Adverse Reactions: Nausea, vomiting, diarrhea, and abdominal discomfort have been reported. The symptoms and signs of potassium intoxication include paresthesias of the extremities, flaccid paralysis, listlessness, mental confusion, weakness and heaviness of the legs, fall in blood pressure, cardiac arrhythmias, and heart block.

Overdosage and Treatment of Hyperkalemia: Hyperkalemia can occur from overdosage or during one of several medical conditions. It should be treated immediately by one or more of the following: 1) Intravenous administration of 300 to 500 ml/hr of 10% dextrose solution containing 10-20 units of crystalline insulin per 1,000 ml. 2) administration of sodium or ammonium cycle exchange resins orally or as retention enemas; 3) hemodialysis or peritoneal dialysis; 4) elimination of potassium containing foods. Caution: Digitalis toxicity can occur if the serum potassium is lowered too rapidly.

How Supplied: Pints and gallons in Grape and Lemon-Lime flavors; 15 ml Stat-Pak and 4 fl. oz. in Grape flavor only.

Vintage potassium that's always in good taste.

Kaon® Elixir
(potassium gluconate)
20 mEq per 15 ml

- Pleasant tasting grape or lemon-lime flavors
- Prescribed with confidence for 26 years
- Well accepted—good patient tolerance
- One tbsp. in 1 oz or more of water supplies 20 mEq potassium (as gluconate)

Adria Laboratories Inc., Columbus, Ohio 43215

BIOVISION

WE'RE
ROUTINE C
INTO C
DIAGNOS

For a relatively small investment, Biovision's CARDIAC STROBE X-ray equipment can add greater diagnostic value to routine chest X-rays. Designed to operate with existing chest X-ray units, it provides a simple, non-invasive screening method for detecting ventricular wall motion abnormalities, valvular defects and shunts.

The idea behind THE CARDIAC STROBE is simple. Using ECG-gating, it captures an image of the heart at both end diastole and end systole during a single cardiac cycle. The resulting serrated image helps measure and evaluate any heart abnormali-

DREAD OF IMPENDING ANGINA

THE INDERAL® PROMISE: FEWER ANGINA ATTACKS SOMETIMES NONE.
(PROPRANOLOL HCl)

The dread of pain. The dread of being hospitalized. The dread of a limited future. That's what angina means to your patient. But with INDERAL, the outlook can brighten.

Inderal: A logical first step. When nitroglycerin and other conventional measures are inadequate, add INDERAL. It counters the anginal hemodynamics. Right at the start, INDERAL diminishes catecholamine-induced rise in heart rate and systolic blood pressure. Reduces myocardial oxygen demand. And brings O_2 supply and demand into more favorable balance.

Inderal: The logic of using it first. Consider these well-documented benefits... Fewer angina attacks—sometimes even none. Less need for nitroglycerin—sometimes no need at all. And greater tolerance for exercise ...greater freedom of action for your patient.

INDERAL®
(PROPRANOLOL HCl)
IN ANGINA PROPHYLAXIS: A LOGICAL CHOICE

INDERAL is contraindicated in patients with bronchial asthma, allergic rhinitis, congestive heart failure, sinus bradycardia, and greater than first degree heart block. Abrupt withdrawal should be avoided.

Please see brief summary of prescribing information on the following page.

THE MOST WIDELY PRESCRIBED BETA BLOCKER IN THE WORLD.

INDERAL®

(PROPRANOLOL HCl)

FOR ANGINA PROPHYLAXIS

BRIEF SUMMARY *(FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE CIRCULAR.)*
Inderal® BRAND OF **PROPRANOLOL HYDROCHLORIDE A beta-adrenergic blocking agent**

BEFORE USING INDERAL (PROPRANOLOL HYDROCHLORIDE), THE PHYSICIAN SHOULD BE THOROUGHLY FAMILIAR WITH THE BASIC CONCEPT OF ADRENERGIC RECEPTORS (ALPHA AND BETA), AND THE PHARMACOLOGY OF THIS DRUG.

CONTRAINDICATIONS

INDERAL is contraindicated in: 1) bronchial asthma; 2) allergic rhinitis during the pollen season; 3) sinus bradycardia and greater than first degree block; 4) cardiogenic shock; 5) right ventricular failure secondary to pulmonary hypertension; 6) congestive heart failure (see WARNINGS) unless the failure is secondary to a tachyarrhythmia treatable with INDERAL; 7) in patients on adrenergic-augmenting psychotropic drugs (including MAO inhibitors), and during the two week withdrawal period from such drugs.

WARNINGS

CARDIAC FAILURE: Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure, and inhibition with beta-blockade always carries the potential hazard of further depressing myocardial contractility and precipitating cardiac failure. INDERAL acts selectively without abolishing the inotropic action of digitalis on the heart muscle (*i.e.*, that of supporting the strength of myocardial contractions). In patients already receiving digitalis, the positive inotropic action of digitalis may be reduced by INDERAL's negative inotropic effect. The effects of INDERAL and digitalis are additive in depressing AV conduction.

IN PATIENTS WITHOUT A HISTORY OF CARDIAC FAILURE, continued depression of the myocardium over a period of time can, in some cases, lead to cardiac failure. In rare instances, this has been observed during INDERAL therapy. Therefore, at the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or given a diuretic, and the response observed closely: a) if cardiac failure continues, despite adequate digitalization and diuretic therapy, INDERAL therapy should be immediately withdrawn; b) if tachyarrhythmia is being controlled, patients should be maintained on combined therapy and the patient closely followed until threat of cardiac failure is over.

IN PATIENTS WITH ANGINA PECTORIS, there have been reports of exacerbation of angina and, in some cases, myocardial infarction, following *abrupt* discontinuation of INDERAL therapy. Therefore, when discontinuance of INDERAL is planned the dosage should be gradually reduced and the patient carefully monitored. In addition, when INDERAL is prescribed for angina pectoris, the patient should be cautioned against interruption or cessation of therapy without the physician's advice. If INDERAL therapy is interrupted and exacerbation of angina occurs, it usually is advisable to reinstitute INDERAL therapy and take other measures appropriate for the management of unstable angina pectoris. Since coronary artery disease may be unrecognized, it may be prudent to follow the above advice in patients considered at risk of having occult atherosclerotic heart disease, who are given propranolol for other indications.

IN PATIENTS WITH THYROTOXICOSIS, possible deleterious effects from long term use have not been adequately appraised. Special consideration should be given to propranolol's potential for aggravating congestive heart failure. Propranolol may mask the clinical signs of developing or continuing hyperthyroidism or complications and give a false impression of improvement. Therefore, abrupt withdrawal of propranolol may be followed by an exacerbation of symptoms of hyperthyroidism, including thyroid storm. This is another reason for withdrawing propranolol slowly. Propranolol does not distort thyroid function tests.

IN PATIENTS WITH WOLFF-PARKINSON-WHITE SYNDROME, several cases have been reported in which, after propranolol, the tachycardia was replaced by a severe bradycardia requiring a demand pacemaker. In one case this resulted after an initial dose of 5 mg propranolol.

IN PATIENTS DURING ANESTHESIA with agents that require catecholamine release for maintenance of adequate cardiac function, beta blockade will impair the desired inotropic effect. Therefore, INDERAL should be titrated carefully when administered for arrhythmias occurring during anesthesia.

IN PATIENTS UNDERGOING MAJOR SURGERY, beta blockade impairs the ability of the heart to respond to reflex stimuli. For this reason, with the exception of pheochromocytoma, INDERAL should be withdrawn 48 hours prior to surgery, at which time all chemical and physiologic effects are gone according to available evidence. However, in case of emergency surgery, since INDERAL is a competitive inhibitor of beta receptor agonists, its effects can be reversed by administration of such agents, *e.g.*, isoproterenol or levarterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has also been reported.

IN PATIENTS PRONE TO NONALLERGIC BRONCHOSPASM (*e.g.*, CHRONIC BRONCHITIS, EMPHYSEMA), INDERAL should be administered with caution since it may block bronchodilation produced by endogenous and exogenous catecholamine stimulation of beta receptors.

DIABETICS AND PATIENTS SUBJECT TO HYPOGLYCEMIA: Because of its beta-adrenergic blocking activity, INDERAL may prevent the appearance of premonitory signs and symptoms (pulse rate and pressure changes) of acute hypoglycemia. This is especially important to keep in mind in patients with labile diabetes. Hypoglycemic attacks may be accompanied by a precipitous elevation of blood pressure.

USE IN PREGNANCY: The safe use of INDERAL in human pregnancy has not been established. Use of any drug in pregnancy or women of childbearing potential requires that the possible risk to mother and/or fetus be weighed against the expected therapeutic benefit. Embryotoxic effects have been seen in animal studies at doses about 10 times the maximum recommended human dose.

PRECAUTIONS

Patients receiving catecholamine depleting drugs such as reserpine should be closely observed if INDERAL is administered. The added catecholamine blocking action of this drug may then produce an excessive reduction of the resting sympathetic nervous activity. Occasionally, the pharmacologic activity of INDERAL may produce hypotension and/or marked bradycardia resulting in vertigo, syncopal attacks, or orthostatic hypotension.

As with any new drug given over prolonged periods, laboratory parameters should be observed at regular intervals. The drug should be used with caution in patients with impaired renal or hepatic function.

ADVERSE REACTIONS

Cardiovascular: bradycardia; congestive heart failure; intensification of AV block; hypotension; paresthesia of hands; arterial insufficiency usually of the Raynaud type; thrombocytopenic purpura

Central Nervous System: lightheadedness; mental depression manifested by insomnia, lassitude, weakness, fatigue; reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics

Gastrointestinal: nausea, vomiting, epigastric distress, abdominal cramping, diarrhea, constipation, mesenteric arterial thrombosis, ischemic colitis

Allergic: pharyngitis and agranulocytosis, erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress

Respiratory: bronchospasm

Hematologic: agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura

Miscellaneous: reversible alopecia. Oculomucocutaneous reactions involving the skin, serous membranes and conjunctivae reported for a beta blocker (practolol) have not been conclusively associated with propranolol.

Clinical Laboratory Test Findings: Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase

DOSAGE AND ADMINISTRATION

The dosage range for INDERAL is different for each indication.

ORAL

ANGINA PECTORIS—*Dosage must be individualized.* Starting with 10-20 mg three or four times daily, before meals and at bedtime, dosage should be gradually increased at three to seven day intervals until optimum response is obtained. Although individual patients may respond at any dosage level, the average optimum dosage appears to be 160 mg per day. In angina pectoris, the value and safety of dosage exceeding 320 mg per day have not been established.

If treatment is to be discontinued, reduce dosage gradually over a period of several weeks. (See WARNINGS.)

PEDIATRIC DOSAGE

At this time the data on the use of the drug in this age group are too limited to permit adequate directions for use.

OVERDOSAGE OR EXAGGERATED RESPONSE

IN THE EVENT OF OVERDOSAGE OR EXAGGERATED RESPONSE, THE FOLLOWING MEASURES SHOULD BE EMPLOYED:

BRADYCARDIA—ADMINISTER ATROPINE (0.25 to 1.0 mg): IF THERE IS NO RESPONSE TO VAGAL BLOCKADE, ADMINISTER ISOPROTERENOL CAUTIOUSLY.

CARDIAC FAILURE—DIGITALIZATION AND DIURETICS

HYPOTENSION—VASOPRESSORS, *e.g.*, LEVARTERENOL OR EPINEPHRINE (THERE IS EVIDENCE THAT EPINEPHRINE IS THE DRUG OF CHOICE).

BRONCHOSPASM—ADMINISTER ISOPROTERENOL AND AMINOPHYLLINE.

HOW SUPPLIED

TABLETS INDERAL (propranolol hydrochloride)

No. 461—Each scored tablet contains 10 mg of propranolol hydrochloride, in bottles of 100 and 1,000. Also in unit dose package of 100.

No. 462—Each scored tablet contains 20 mg of propranolol hydrochloride, in bottles of 100 and 1,000. Also in unit dose package of 100.

No. 464—Each scored tablet contains 40 mg of propranolol hydrochloride, in bottles of 100 and 1,000. Also in unit dose package of 100.

No. 468—Each scored tablet contains 80 mg of propranolol hydrochloride, in bottles of 100 and 1,000. Also in unit dose package of 100.

INJECTABLE

No. 3265—Each ml contains 1 mg of propranolol hydrochloride in Water for Injection. The pH is adjusted with citric acid. Supplied as: 1 ml ampuls in boxes of 10.

HEARTS AND HEART-LIKE ORGANS

Edited by GEOFFREY H. BOURNE

This detailed treatise constitutes an anatomical and physiological survey of the heart from invertebrates to humans. Volume 1 outlines the development and evolution of the heart from the invertebrates and the lower vertebrates up through humans. Volume 2 deals with the physiology of the heart, the effects of hormones, exercise, stress, bedrest, and hypoxia, and the control of the coronary system. Volume 3 considers the pathology and surgery of the heart, viruses of the heart, and the status of cardiac surgery and cardiac transplantation. Future volumes are planned to cover heart attacks and the fundamentals of the structure and functioning of the cardiac cell among other topics. *Hearts and Heart-Like Organs* provides a basis for the continued study of the heart and facilitates a greater understanding of its complexities. It will serve to stimulate ideas for future research on this vital organ.

Volume 1: COMPARATIVE ANATOMY AND DEVELOPMENT

CHAPTER HEADINGS: *A. W. Martin*, Some Invertebrate Myogenic Hearts: The Hearts of Worms and Molluscs. *D. J. Randall and P. S. Davie*, The Hearts of Urochordates and Cephalochordates. *K. Johansen and W. Burggren*, Cardiovascular Function in the Lower Vertebrates. *A. Yamauchi*, Fine Structure of the Fish Heart. *Y.-i. Satoh and T. Nitatori*, On the Fine Structure of Lymph Hearts in Amphibia and Reptiles. *A. Martínez-Palomo and J. Alanís*, The Amphibian and Reptilian Hearts: Impulse Propagation and Ultrastructure. *J. B. Cabot and D. H. Cohen*, Neural Control of the Avian Heart. *U. Rowlatt*, Functional and Nonfunctional Determinants of Mammalian Cardiac Anatomy, Parts I and II. *K. Rakusan*, Postnatal Development of the Heart. *V. Navaratnam*, Anatomy of the Mammalian Heart. *J. E. Skandalakis et al.*, The Anatomy of the Human Pericardium and Heart. Index.
Each chapter contains references.
1980, 432 pp., $51.00 ISBN: 0-12-119401-9
*Subscription Price: $43.50**

Volume 2: PHYSIOLOGY

CHAPTER HEADINGS: *A. M. Lefer and G. J. Trachte*, Effects of Hormones on the Heart. *A. Wennmalm*, Prostaglandins and the Heart. *R. C. Smallridge*, Thyroid Hormone Effects on the Heart. *W. M. Manger*, Catecholamines and the Heart. *H. I. Russek and L. G. Russek*, Emotion and the Heart. *H. Selye*, The Nature of Stress and Its Relation to Cardiovascular Disease. *P. R. Moret*, Hypoxia and the Heart. *H. Lowell Stone*, The Heart and Exercise Training. *R. T. Dowell*, Cardiac Hypertrophy. *H. Sandler*, Effects of Bedrest and Weightlessness on the Heart. *G. Marchetti*, Chemical and Nervous Control of the Coronary System. Index.

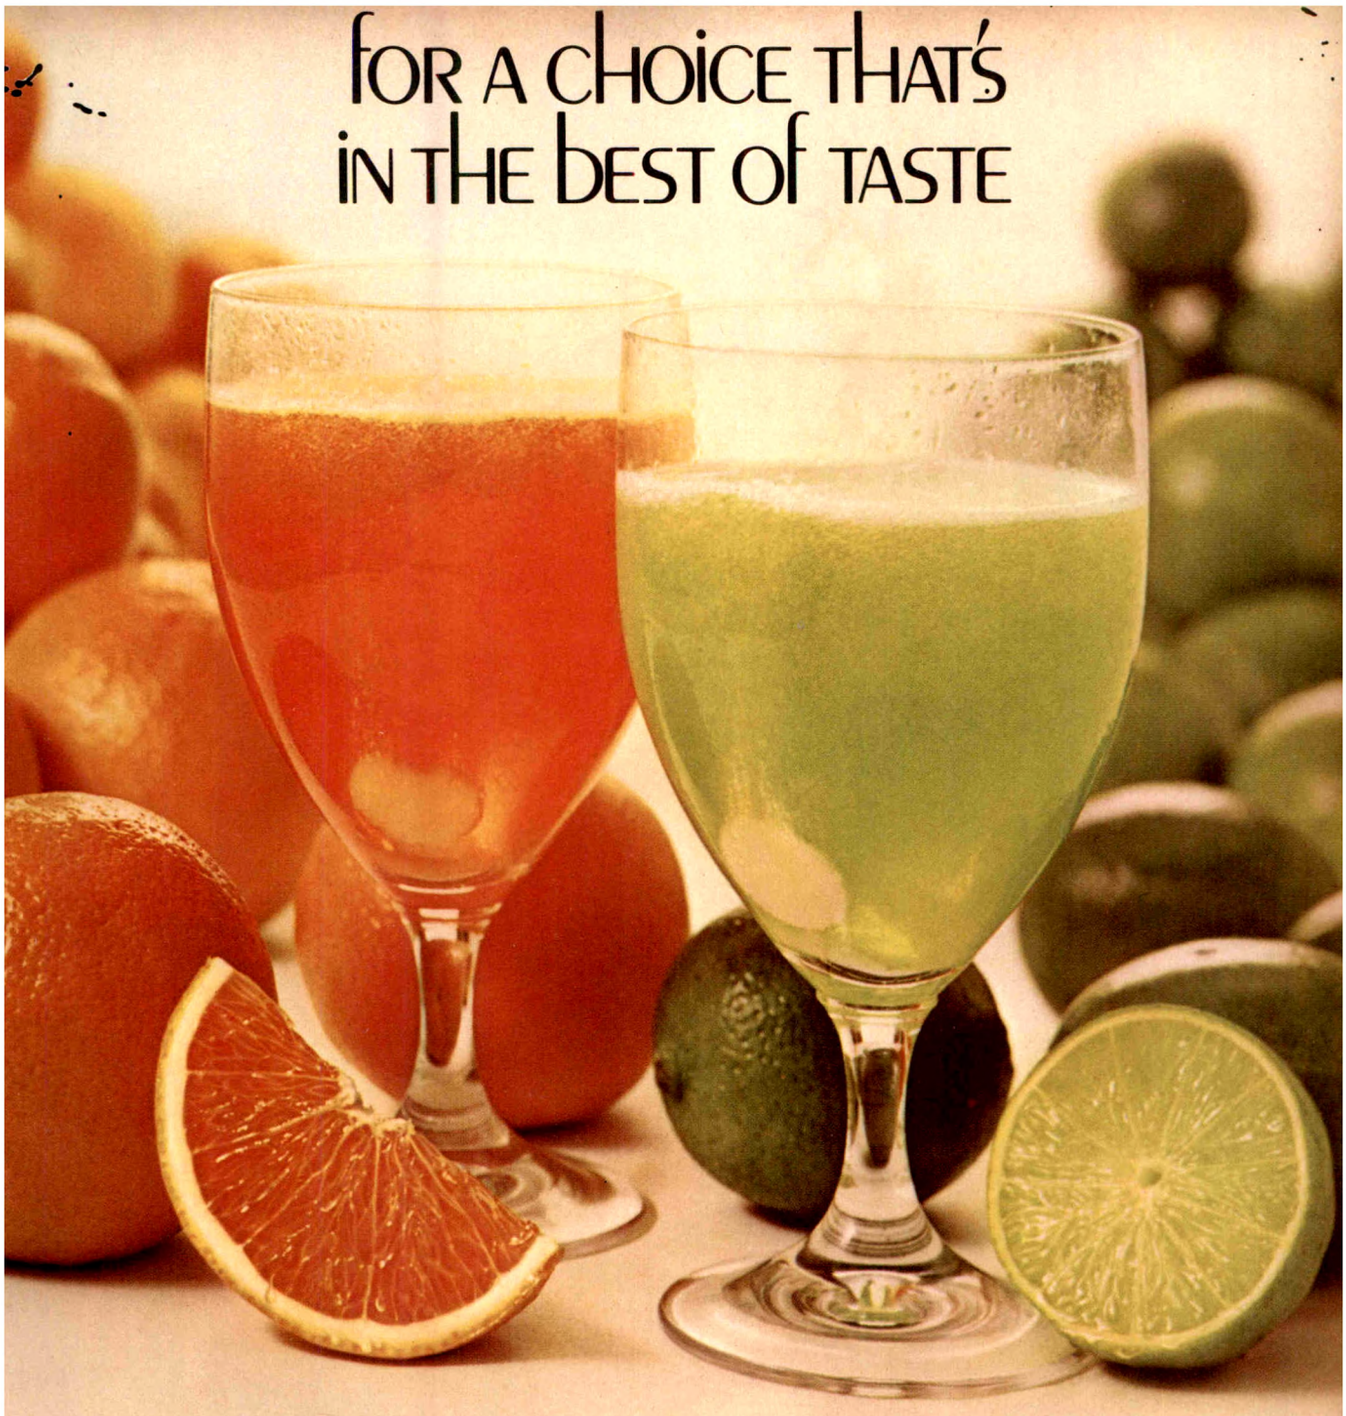
FOR A CHOICE THAT'S IN THE BEST OF TASTE



K-LYTE®

Each effervescent tablet in solution supplies 25 mEq potassium as bicarbonate and citrate

Orange and Lime Flavors
The best of taste for over a decade

K-LYTE® DS

Each effervescent tablet in solution supplies 50 mEq potassium as bicarbonate and citrate

Orange and Lime Flavors
Convenient once-a-day dosage

Prescribing Considerations

Indications: K-LYTE DS and K-LYTE are oral potassium supplements for therapy or prophylaxis of potassium deficiency. They are particularly useful when thiazide diuretics, corticosteroids, or severe vomiting and diarrhea cause excessive excretory potassium losses; and when dietary potassium is low. Carefully monitored, K-LYTE DS and K-LYTE may also be useful for potassium replacement where digitalis intoxication results in cardiac arrhythmias.

Contraindications: Impaired renal function with oliguria or azotemia; Addison's disease; hyperkalemia from any cause.

Warnings and Precautions: Since the amount of potassium deficiency may be difficult to determine accurately, supplements should be administered with caution, and dosages adjusted to the requirements of the individual patient. Potassium intoxication rarely occurs in patients with normal kidney function. Symptoms of potassium intoxication are variable. They include listlessness, mental confusion, and tingling of the extremities. Frequent checks of the clinical status of the patient, ECG, and serum potassium level are desirable. In established hypokalemia, attention should also be directed toward other potential electrolyte disturbances. Potassium supplements should be given cautiously to digitalized patients and such patients should be monitored by ECG for cardiac irregularities. To minimize the possibility of gastrointestinal irritation associated with the oral ingestion of concentrated potassium salt preparations, **patients should be carefully directed to dissolve each dose completely in the stated amount of water.**

Adverse Reactions: Nausea, vomiting, diarrhea, and abdominal discomfort may occur with the use of potassium salts.

Dosage and Administration: Adults: 1 K-LYTE DS tablet (50 mEq potassium) completely dissolved in 6 to 8 ounces of cold or ice water, 1 to 2 times daily; 1 K-LYTE tablet (25 mEq potassium) completely dissolved in 3 to 4 ounces of cold or ice water, 2 to 4 times daily. **NOTE: It is suggested that K-LYTE DS and K-LYTE be taken with meals and sipped slowly over a 5 to 10 minute period.**

How Supplied: K-LYTE DS effervescent tablets (orange or lime flavors) are available in cartons of 30 and 100. K-LYTE effervescent tablets (orange or lime flavors) are available in cartons of 30 and 250. All tablets are individually foil wrapped.

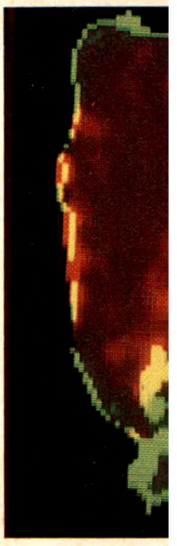
world's first digital camera designed for the cardiologist

pex 215M: lightweight mobile cardiological gamma image

Apex 215M is a fully integrated nuclear system designed specifically for the cardiologist.
Apex 215M fulfills all the requirements of modern nuclear cardiology. Compact, exceptionally maneuverable, easy to position and extremely versatile, it combines superb single-crystal image quality with the ultra-high count rates previously obtainable only with low-resolution multicrystal cameras.



elscint inc.

138-160 Johnson Avenue,
Hackensack, N.J. 07602, U.S.A.

Call toll Free: 800-631-1694

Universal Cardiological Capability

Crystal Clear First-Pass Examinations at count rates as high as 500,000 CPS and resolutions as fine as 3.8 mm (bar phantom). Unobstructed RAO dynamic views of distinct clarity.
Ultra-Fast Equilibrium Gated Dynamics at unprecedented combinations of frame rate and resolution (64 frames per heart cycle for 64^2 matrices), at rest or during exercise.
Superior Quality Static Myocardial Imaging with either ^{99}Tc pyrophosphate or ^{201}Tl. Images acquired and displayed on 512^2 matrices with 256 gray levels.

A Set of Dedicated Cardiological Programs, Continuously Enriched

Touch a functional pushbutton, and Apex 215M provides:

- Up to three simultaneous cine-views.
- Wall motion visualization and quantification.
- Ejection Fraction and Ejection Rate calculation.
- Remaining Fraction calculation.
- Static or dynamic Regional Ejection Fraction Imaging.
- End Diastole/Systole Volumes.
- Shunt quantification.

Programs unique to the Apex Line include special algorithms for diagnosing ventricular-atrial regurgitation and ventricular aneurysms. A whole new series of Apex clinical programs is now being tested.

Dobutrex®
Dobutamine HCl

For I.V. Injection
250 mg* in 20-ml-size vials
* Equivalent to dobutamine

Brief Summary
Consult the package literature for prescribing information.

Indications and Usage: Dobutrex® (dobutamine hydrochloride, Lilly) is indicated when parenteral therapy is necessary for inotropic support in the short-term treatment of adults with cardiac decompensation due to depressed contractility resulting either from organic heart disease or from cardiac surgical procedures.

In patients who have atrial fibrillation with rapid ventricular response, a digitalis preparation should be used prior to instituting therapy with Dobutrex.

Contraindication: Dobutrex is contraindicated in patients with idiopathic hypertrophic subaortic stenosis.

Warnings: 1. *Increase in Heart Rate or Blood Pressure*—Dobutrex may cause a marked increase in heart rate or blood pressure, especially systolic pressure. Approximately 10 percent of patients in clinical studies have had rate increases of 30 beats/minute or more, and about 7.5 percent have had a 50-mm Hg or greater increase in systolic pressure. Reduction of dosage usually reverses these effects promptly. Because dobutamine facilitates atrioventricular conduction, patients with atrial fibrillation are at risk of developing rapid ventricular response. Patients with preexisting hypertension appear to face an increased risk of developing an exaggerated pressor response.

2. *Ectopic Activity*—Dobutrex may precipitate or exacerbate ventricular ectopic activity, but it rarely has caused ventricular tachycardia.

Precautions: 1. **During the administration of Dobutrex, as with any adrenergic agent, ECG and blood pressure should be continuously monitored. In addition, pulmonary wedge pressure and cardiac output should be monitored whenever possible to aid in the safe and effective infusion of Dobutrex.**

2. Hypovolemia should be corrected with suitable volume expanders before treatment with Dobutrex is instituted.

3. Animal studies indicate that Dobutrex may be ineffective if the patient has recently received a beta-blocking drug. In such a case, the peripheral vascular resistance may increase.

4. No improvement may be observed in the presence of marked mechanical obstruction, such as severe valvular aortic stenosis.

Usage Following Acute Myocardial Infarction—Clinical experience with Dobutrex following myocardial infarction has been insufficient to establish the safety of the drug for this use. There is concern that any agent which increases contractile force and heart rate may increase the size of an infarction by intensifying ischemia, but it is not known whether dobutamine does so.

Usage in Pregnancy—Reproduction studies performed in rats and rabbits have revealed no evidence of impaired fertility, harm to the fetus, or teratogenic effects due to dobutamine. However, the drug has not been administered to pregnant women and should be used only when the expected benefits clearly outweigh the potential risks to the fetus.

Pediatric Use—The safety and effectiveness of Dobutrex® (dobutamine hydrochloride, Lilly) for use in children have not been studied.

Drug Interactions—There was no evidence of drug interactions in clinical studies in which Dobutrex was administered concurrently with other drugs, including digitalis preparations, furosemide, spironolactone, lidocaine, glyceryl trinitrate, isosorbide dinitrate, morphine, atropine, heparin, protamine, potassium chloride, folic acid, and acetaminophen. Preliminary studies indicate that the concomitant use of dobutamine and nitroprusside results in a higher cardiac output and, usually, a lower pulmonary wedge pressure than when either drug is used alone.

Adverse Reactions: *Increased Heart Rate, Blood Pressure, and Ventricular Ectopic Activity*—A 10 to 20-mm increase in systolic blood pressure and an increase in heart rate of five to 15 beats per minute have been noted in most patients. (See Warnings regarding exaggerated chronotropic and pressor effects.) Approximately 5 percent of patients have had increased premature ventricular beats during infusions. These effects are dose related.

Miscellaneous Uncommon Effects—The following adverse effects have been reported in 1 to 3 percent of patients: nausea, headache, anginal pain, nonspecific chest pain, palpitations, and shortness of breath.

No abnormal laboratory values attributable to Dobutrex have been observed.

Longer-Term Safety—Infusions of up to 72 hours have revealed no adverse effects other than those seen with shorter infusions.

Overdosage: In case of overdosage, as evidenced by excessive alteration of blood pressure or by tachycardia, reduce the rate of administration or temporarily discontinue Dobutrex until the patient's condition stabilizes. Because the duration of action of Dobutrex is short, usually no additional remedial measures are necessary.

Administration and Dosage: *Reconstitution and Stability*—Dobutrex® (dobutamine hydrochloride, Lilly) is incompatible with alkaline solutions and should not be mixed with products such as 5% Sodium Bicarbonate Injection.

Dobutrex may be reconstituted with Sterile Water for Injection or 5% Dextrose Injection. To reconstitute, add 10 ml of diluent to Vial No. 7051, Dobutrex, 250 mg. If the material is not completely dissolved, add an additional 10 ml of diluent. The reconstituted solution may be stored under refrigeration for 48 hours or at room temperature for six hours.

Reconstituted Dobutrex must be further diluted to at least 50 ml prior to administration in 5% Dextrose Injection, 0.9% Sodium Chloride Injection, or Sodium Lactate Injection. Intravenous solutions should be used within 24 hours.

Solutions containing Dobutrex may exhibit a color that, if present, will increase with time. This color change is due to slight oxidation of the drug, but there is no significant loss of potency during the reconstituted time periods stated above.

Recommended Dosage—The rate of infusion needed to increase cardiac output usually ranges from 2.5 to 10 mcg/kg/min (see table). On rare occasions, infusion rates up to 40 mcg/kg/min have been required to obtain the desired effect.

Rates of Infusion for Concentrations of 250,500, and 1000 mcg/ml

Drug Delivery Rate (mcg/kg/min)	Infusion Delivery Rate 250 mcg/ml* (ml/kg/min)	500 mcg/ml† (ml/kg/min)	1000 mcg/ml‡ (ml/kg/min)
2.5	0.01	0.005	0.0025
5	0.02	0.01	0.005
7.5	0.03	0.015	0.0075
10	0.04	0.02	0.01
12.5	0.05	0.025	0.0125
15	0.06	0.03	0.015

*250 mg per liter of diluent
†500 mg per liter or 250 mg per 500 ml of diluent
‡1000 mg per liter or 250 mg per 250 ml of diluent

The rate of administration and the duration of therapy should be adjusted according to the patient's response, as determined by heart rate, presence of ectopic activity, blood pressure, urine flow, and, whenever possible, measurement of central venous or pulmonary wedge pressure and cardiac output.

Concentrations up to 5000 mcg/ml have been administered to humans (250 mg/50 ml). The final volume administered should be determined by the fluid requirements of the patient.

TREATING MYOCARDIAL INFARCTION AND REDUCING THE THREAT OF THROMBOEMBOLISM

Each year in this country approximately one million people suffer acute myocardial infarctions. Rapid emergency treatment in coronary care units has been credited with reducing by up to one third the mortality among patients hospitalized with acute attacks.[1]

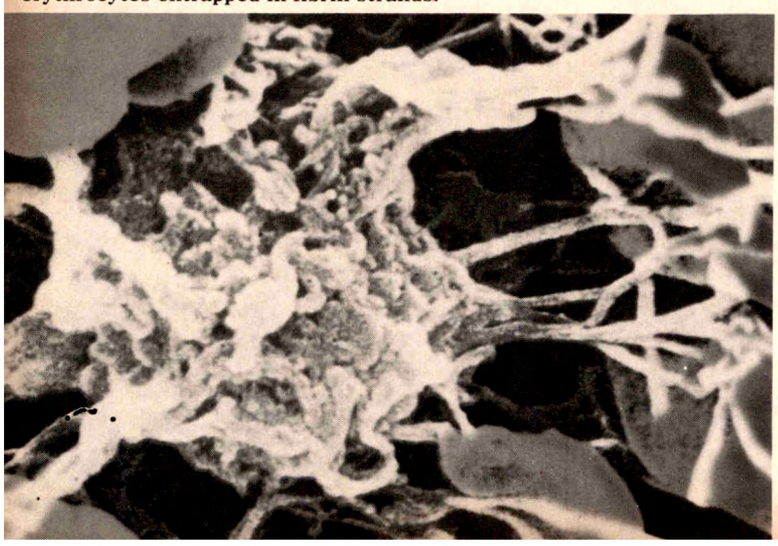
Thrombosis—incidence in myocardial infarction Following the damage to the heart itself, thromboembolism is perhaps the most serious sequel to myocardial infarction.

A study has demonstrated that there is a 39% incidence of calf vein thrombosis during the acute phase of myocardial infarction.[1]

Speed saves lives It has been reported that more than half the thrombi destined to occur in the calf veins form within 72 hours of myocardial infarction, and three-fourths form within the first week. Therefore, a number of investigators have recommended that antithrombotic measures should begin upon admission to the hospital and be effective almost immediately.[2]

Oral anticoagulants have a clinical value It has also been stated that the use of anticoagulants may reduce the frequency of calf vein thrombosis from 22 to 6.5%. The use of anticoagulants is subject to differing opinions regarding improved survival. A number of authorities recommend the use of anticoagulants in *all* patients who have no specific contraindications during the period of hospitalization.[1]

Scanning electron micrograph of 'Red' thrombus, formed by erythrocytes entrapped in fibrin strands.



One team of investigators in M.I. recommends providing full-dose warfarin while the patient is in the hospital and for several days afterward—

if the patient has had prior infarcts or thromboembolism
if the area of infarction is large
if complications (such as CHF or hypotension) require prolonged bed rest.

But, if post myocardial infarction syndrome (Dressler's syndrome) develops, anticoagulants should be discontinued, as pericardial hemorrhage or even cardiac tamponade may develop.[1]

Objectives and benefits of anticoagulation The use of anticoagulants in the acute phase of myocardial infarction has these potential advantages:[2]

prevention of deep vein thrombosis
reduction of embolization from cardiac mural thrombi
prophylaxis against extension of myocardial necrosis or long-term recurrence of infarction
reduction of overall mortality

If anticoagulants can inhibit the formation of deep vein thrombi, then the incidence of pulmonary embolism might be diminished—and pulmonary embolism has been estimated as a threat to life in 5,000 of the 500,000 myocardial infarction patients who are admitted to hospitals in this country each year.[2]

A look at survival One retrospective study of the use of anticoagulants in M.I. evaluated the survival of 1,307 patients from 20 hospitals in a large metropolitan community. The diagnosis of M.I. was based on predefined criteria, which included typical chest pain, serial ECG's, enzyme elevations, and autopsy findings.

Among anticoagulated patients, the adjusted in-hospital case-fatality rate was 18%. For patients who did not receive this treatment, the fatality rate was 31%. For survivors followed for as long as ten years, patients who had been anticoagulated still fared better than those not so treated.[3]

The authors of this study recognize

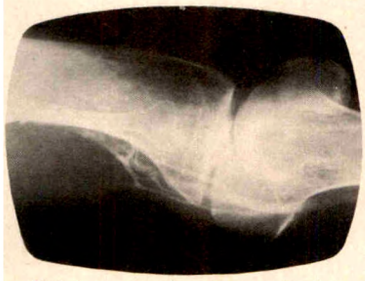
the drawbacks of using retrospective evidence and call for the formation of a multi-center, double-blind, randomized study on the use of anticoagulants in acute myocardial infarction.

Screening the high risk group The risk of DVT (deep vein thrombosis) is particularly great among certain patient groups:

- patients with left ventricular failure
- patients in shock
- patients with arrhythmias
- older patients
- obese patients
- patients with varicose veins
- patients with previous myocardial infarction or thromboembolism

Screening techniques Diagnosis of DVT by physical examination may miss a significant number of clinically silent thrombi. There are, however, additional technological tools to help the clinician define more accurately the incidence of deep vein thrombosis. Among these are:

iodine-125 fibrinogen scanning—radioactively tagged fibrinogen is incorporated into actively forming thrombi and is detected on external sensors. This method is accurate for popliteal and calf vein thrombi, but not for iliofemoral thrombi.[2]



Phlebogram showing occlusion in deep vein of the upper calf.

venography—radiographic evidence of DVT is seen as a constant filling defect in venous projections, abrupt termination of a column of contrast material at a constant site, nonfilling of the deep veins, and presence of flow in collateral veins.[4]

ultrasound—Doppler ultrasound scanning can provide a fast, convenient, inexpensive reading of deep venous obstruction. This technique is potentially the most versatile and accurate method available. However, it demands considerable operator experience to insure maximal accuracy.[5]

impedance plethysmography—this technique results from the observation that blood volume changes in the calf produced by inflation or deflation of a thigh cuff produce variations in electrical resistance (impedance). Such changes are reduced in patients with thrombosis of the popliteal or more proximal veins.[4]

Patient compliance through education Providing the anticoagulated patient with information about his altered physical state and motivating him to comply with the therapeutic regimen constitute one of the most important aspects of health care.[6]

To determine the best way of imparting necessary information about anticoagulation to patients, a test was devised. One group of patients was given a brochure detailing the need for the medication and the importance of following the doctor's instructions. A second group of patients was given a programmed instruction booklet which was quite comprehensive in its teaching content, which included the action of warfarin, the purpose of prothrombin times, how to figure dosage from tablet strengths, possible complications and steps to take to control them.

When tested for learning and retention, the patients in the programmed instruction group scored significantly higher than the group given brochures only. In an area of medicine that relies so heavily on patient compliance, this report could be important in determining how medical information is communicated to the patient.[6]

The bottom line A postmortem study[7] underlines the importance of thrombosis in myocardial infarction. In this study of 173 patients with recurrent myocardial infarction, coronary occlusion due to thrombosis occurred in 54% of cases. Recent occlusive coronary thrombosis was 4 times less frequent in patients who received adequate anticoagulation (mean prothrombin level was 29 ± 5%).

And as one authority states:

"Rational use of anticoagulant therapy in the setting of acute myocardial infarction may save more than 8,000 lives a year in this country. Full advantage should be taken of this therapeutic opportunity."[2]

COUMADIN is an Endo registered U.S. trademark.

COUMADIN®

crystalline warfarin sodium, U.S.P.*

TABLETS

DESCRIPTION COUMADIN (crystalline warfarin sodium), a prothrombinopenic anticoagulant, is chemically crystalline sodium warfarin isopropanol clathrate. The crystallization of warfarin sodium virtually eliminates trace impurities present in amorphous warfarin sodium, thus achieving a crystalline product of the highest purity. Warfarin* is the coined generic name for 3-(α-Acetonylbenzyl)-4-hydroxycoumarin. On a dose-for-dose basis, COUMADIN (crystalline warfarin sodium) is therapeutically equivalent to amorphous warfarin sodium.

ACTIONS COUMADIN and other coumarin anticoagulants act by depressing synthesis in the liver of several factors which are known to be active in the coagulation mechanisms in a variety of diseases characterized by thromboembolic phenomena. The resultant **in vivo** effect is a sequential depression of Factors VII, IX, X and II. The degree of depression is dependent upon the dosage administered. Anticoagulants have no direct effect on an established thrombus, nor do they reverse ischemic tissue damage. However, once a thrombosis has occurred, anticoagulant treatment aims to prevent further extension of the formed clot and prevents secondary thromboembolic complications which may result in serious and possible fatal sequelae.

After oral administration, absorption is essentially complete, and maximal plasma concentrations are reached in 1 to 9 hours. Approximately 97% is bound to albumin within the plasma. COUMADIN (crystalline warfarin sodium) usually induces hypoprothrombinemia in 36 to 72 hours, and its duration of action may persist for 4 to 5 days, thus producing a smooth, long lasting response curve. Little is known of the metabolic pathways involved in the biotransformation of oral anticoagulants in man. However, their metabolites appear to be eliminated principally in the urine.

INDICATIONS Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

Effective: COUMADIN is indicated for the prophylaxis and treatment of venous thrombosis and its extension, the treatment of atrial fibrillation with embolization, the prophylaxis and treatment of pulmonary embolism, and as an adjunct in the treatment of coronary occlusion.

"Possibly" effective: as an adjunct in the treatment of transient cerebral ischemic attacks.

Final classification of the less-than-effective indication requires further investigation.

CONTRAINDICATIONS Anticoagulation is contraindicated in any localized or general physical condition or personal circumstance in which the hazard of hemorrhage might be greater than its potential clinical benefits, such as:

Pregnancy—COUMADIN (crystalline warfarin sodium) is contraindicated in pregnancy because the drug passes through the placental barrier and may cause fatal hemorrhage to the fetus in utero. Furthermore, there have been reports of birth malformations in children born to mothers who have been treated with warfarin during pregnancy. Women of childbearing potential who are candidates for anticoagulant therapy should be carefully evaluated and the indications critically reviewed with the patient. If the patient becomes pregnant while taking this drug, she should be apprised of the potential risks to the fetus, and the possibility of termination of the pregnancy should be discussed in light of those risks.

Hemorrhagic tendencies or blood dyscrasias. Recent or contemplated surgery of: (1)central nervous system; (2)eye; (3)traumatic surgery resulting in large open surfaces. **Bleeding tendencies associated with active ulceration or overt bleeding of:** (1)gastrointestinal, genitourinary or respiratory tracts; (2)cerebrovascular hemorrhage; (3)aneurysms—cerebral, dissecting aorta; (4)pericarditis and pericardial effusions; (5)subacute bacterial endocarditis. **Threatened abortion,** eclampsia and preeclampsia. **Inadequate laboratory facilities** or unsupervised senility, alcoholism, psychosis; or lack of patient cooperation. **Spinal puncture** and other diagnostic or therapeutic procedures with potential for uncontrollable bleeding. **Miscellaneous:** major regional, lumbar block anesthesia and malignant hypertension.

WARNINGS Warfarin sodium is a potent drug with a half-life of 2½ days; therefore its effects may become more pronounced as daily maintenance doses overlap. It cannot be emphasized too strongly that treatment of each patient is a highly individualized matter. Dosage should be controlled by periodic determinations of prothrombin time or other suitable coagulation tests. Determinations of whole blood clotting and bleeding times are not effective measures for control of therapy. Heparin prolongs the one-stage prothrombin time. Therefore, to obtain a valid prothrombin time when heparin and COUMADIN (crystalline warfarin sodium) are given together, a period of at least 5 hours should elapse after the last intravenous dose and 24 hours after the last subcutaneous dose of heparin, before blood is drawn.

Caution should be observed when warfarin sodium is administered in any situation or physical condition where added risk of hemorrhage is present.

Administration of anticoagulants in the following conditions will be based upon clinical judgment in which the risks of anticoagulant therapy are weighed against the risk of thrombosis or embolization in untreated cases. The following may be associated with these increased risks:

Lactation—coumarins may pass into the milk of mothers and cause a prothrombinopenic state in the nursing infant. **Severe to moderate hepatic or renal insufficiency. Infectious diseases or disturbances of intestinal flora**—sprue, antibiotic therapy. **Trauma** which may result in internal bleeding. **Surgery or trauma** resulting in large exposed raw surfaces. **Indwelling catheters. Severe to moderate hypertension. Miscellaneous:** polycythemia vera, vasculitis, severe diabetes, severe allergic and anaphylactic disorders.

Patients with congestive heart failure may become more sensitive to COUMADIN, thereby requiring more frequent laboratory monitoring, and reduced doses of COUMADIN.

Concurrent use of anticoagulants with streptokinase or urokinase is not recommended and may be hazardous. (Please note recommendations accompanying these preparations.)

Abrupt cessation of anticoagulant therapy is not generally recommended; taper dose gradually over three to four weeks.

PRECAUTIONS Periodic determination of prothrombin time or other suitable coagulation test is essential.

Numerous factors, alone or in combination, including travel, changes in diet, environment, physical state and medication may influence response of the patient to anticoagulants. It is generally good practice to monitor the patient's response with additional prothrombin time determinations in the period immediately after discharge from the hospital, and whenever other medications are initiated, discontinued or taken haphazardly. The following factors are listed for your reference; however, other factors may also affect the prothrombin response.

The following factors, alone or in combination, may be responsible for increased prothrombin time response:

ENDOGENOUS FACTORS: Carcinoma; collagen disease; congestive heart failure; diarrhea; elevated temperature; hepatic disorders—infectious hepatitis, jaundice; poor nutritional state; vitamin K deficiency—steatorrhea.

EXOGENOUS FACTORS: Alcohol†; allopurinol; aminosalicylic acid; anabolic steroids; antibiotics; chymotrypsin; chloral hydrate†; chlorpropamide; chymotrypsin; cimetidine; cinchophen; clofibrate; COUMADIN (crystalline warfarin sodium) overdosage; dextran; dextrothyroxine; diazoxide; dietary deficiencies; diuretics†; disulfiram; drugs affecting blood elements, ethacrynic acid; glucagon; hepatotoxic drugs; indomethacin; inhalation anesthetics; mefenamic acid; methyldopa; methylphenidate; metronidazole; monoamine oxidase inhibitors; nalidixic acid; oxolinic acid; oxyphenbutazone; pyrazolones; phenylbutazone; phenyramidol; phenytoin; prolonged hot weather; prolonged narcotics; quinidine; quinine; salicylates; sulfinpyrazone; sulfonamides, long acting; sulindac; thyroid drugs; tolbutamide; triclofos sodium; trimethoprim/sulfamethoxazole; unreliable prothrombin time determinations.

†Present as crystalline sodium warfarin isopropanol clathrate.

†Increased and decreased prothrombin time responses have been reported.

The following factors, alone or in combination, may be responsible for decreased prothrombin time response:

ENDOGENOUS FACTORS: Edema; hereditary resistance to coumarin therapy; hyperlipemia; hypothyroidism.

EXOGENOUS FACTORS: Adrenocortical steroids; alcohol†; antacids; antihistamines; barbiturates; chloral hydrate†; chlordiazepoxide; cholestyramine; COUMADIN (crystalline warfarin sodium) underdosage; diet high in vitamin K; diuretics†; ethchlorvynol; glutethimide; griseofulvin; haloperidol; meprobamate; oral contraceptives; paraldehyde; primidone; rifampin; unreliable prothrombin time determinations; vitamin C.

†Increased and decreased prothrombin time responses have been reported.

A patient may be exposed to a combination of the above factors, some of which may increase and some decrease his sensitivity to COUMADIN. Because the net effect on his prothrombin time response may be unpredictable under these circumstances, more frequent laboratory monitoring is advisable.

Drugs not yet shown to interact or not to interact with coumarins are best regarded with suspicion, and when their administration is started or stopped, the prothrombin time should be determined more often than usual.

Coumarins also affect the action of other drugs. Hypoglycemic agents (chlorpropamide and tolbutamide) and anticonvulsants (phenytoin and phenobarbital) may accumulate in the body as a result of interference with either their metabolism or excretion.

ADVERSE REACTIONS Potential side effects of COUMADIN (crystalline warfarin sodium) include:

1. Minor or major hemorrhage from any tissue or organ—which is an extension of the physiologic activity of prothrombinopenia. The signs and symptoms will vary according to the location and degree or extent of the bleeding. Therefore the possibility of hemorrhage should be considered in evaluating the condition of any anticoagulated patient with complaints which do not indicate an obvious diagnosis. Bleeding during anticoagulant therapy does not always correlate with prothrombin activity. (See TREATMENT FOR OVERDOSAGE.)

Bleeding which occurs when the prothrombin time is within the therapeutic range warrants diagnostic investigation since it may unmask a previously unsuspected lesion, e.g. tumor, ulcer, etc.

2. Side effects other than hemorrhage are infrequent and consist of alopecia, urticaria, dermatitis, fever, nausea, diarrhea, abdominal cramping, a syndrome called "purple toes," hypersensitivity reactions and a reaction consisting of hemorrhagic infarction and necrosis of the skin.

3. Priapism has been associated with anticoagulant administration, however, a causal relationship has not been established.

DOSAGE AND LABORATORY CONTROL The aim of anticoagulant therapy is to impede the coagulation or clotting mechanism to such an extent that thrombosis will not occur, but at the same time avoiding such extensive impairment as might produce spontaneous bleeding. Effective therapeutic levels with minimal complications can best be achieved in cooperative and well-instructed patients, who keep the doctor informed of their status between visits. COUMADIN (crystalline warfarin sodium) patient aids are available to physicians on request.

The administration and dosage of COUMADIN must be individualized for each patient according to the particular patient's sensitivity to the drug as indicated by the prothrombin time. The prothrombin time reflects the depression of vitamin K dependent Factors VII, X and II. These factors, in addition to Factor IX, are affected by coumarin anticoagulants. There are several modifications of the Quick one-stage prothrombin time and the physician should become familiar with the specific method used in his laboratory.

Administration of COUMADIN should be gauged according to prothrombin time determinations by a suitable method. The blood prothrombin time should usually be determined daily after the administration of the initial dose until prothrombin time results stabilize in the therapeutic range. Intervals between subsequent prothrombin time determinations should be based upon the physician's judgment of the patient's reliability and response to warfarin in order to maintain the individual within the therapeutic range. Acceptable intervals for prothrombin time determinations have usually fallen within the range of one to four weeks. Satisfactory levels for maintenance of therapeutic anticoagulation are 1½ to 2½ times the normal prothrombin time (e.g. 18 to 30 seconds, with a control of 12 seconds).

Induction—40 to 60 mg for average adult or 20 to 30 mg for elderly and/or debilitated patients for one dose only administered orally, intravenously or intramuscularly.

Alternatively, the large priming dose may be decreased for all patients to minimize the possibility of excessive increases in prothrombin time. Induction may be initiated with 10 to 15 mg daily and thereafter (usually 2 or 3 days) adjusted according to prothrombin time response. The basis for the no-loading dose regimen is that the depression of Factors II, IX, and X is not accelerated by the administration of a loading dose.

Maintenance—Most patients are satisfactorily maintained at a dose of 2 to 10 mg daily. Flexibility of dosage is provided by breaking scored tablets in half. The individual dose and interval should be gauged by the patient's prothrombin response.

Duration of therapy—The duration of therapy in each patient should be individualized. In general, anticoagulant therapy should be continued until the danger of thrombosis and embolism has passed.

Treatment during dentistry and surgery—The management of patients who undergo dental and surgical procedures requires close liaison between attending physicians, surgeons and dentists. Interruption of anticoagulant therapy may precipitate thromboembolism, and conversely, if anticoagulants are maintained at full doses, some patients may hemorrhage excessively. If it is elected to administer anticoagulants prior to, during, or immediately following dental or surgical procedures, it is recommended that the dosage of COUMADIN (crystalline warfarin sodium) be adjusted to maintain the prothrombin time at approximately 1½ to 2½ times the control level. The operative site should be sufficiently limited to permit the effective use of local procedures for hemostasis including absorbable hemostatic agents, sutures, and pressure dressings if necessary. Under these conditions dental and surgical procedures may be performed without undue risk of hemorrhage.

COUMADIN with Heparin—Since a delay intervenes between the administration of the initial dose and the therapeutic prolongation of prothrombin time, it may be advisable in emergency situations to administer sodium heparin initially along with COUMADIN. The initial dose of heparin and injectable COUMADIN may be administered together in the same syringe.

It should be noted that heparin may affect the prothrombin time, and therefore, when patients are receiving both heparin and COUMADIN, the blood sample for prothrombin time determination should be drawn just prior to the next heparin dosage, at least 5 hours after the last intravenous injection or 24 hours after the last subcutaneous injection.

TREATMENT FOR OVERDOSAGE Excessive prothrombinopenia, with or without bleeding, is readily controlled by discontinuing COUMADIN (crystalline warfarin sodium), and if necessary, the oral or parenteral administration of vitamin K_1. The appearance of microscopic hematuria, excessive menstrual bleeding, melena, petechiae or oozing from nicks made while shaving are early manifestations of hypoprothrombinemia beyond a safe and satisfactory level.

In excessive prothrombinopenia with mild or no bleeding, omission of one or more doses of COUMADIN may suffice; and if necessary, small doses of vitamin K_1 orally, 2.5 to 10 mg, will usually correct the problem.

If minor bleeding persists, or progresses to frank bleeding, vitamin K_1 in doses of 5 to 25 mg may be given parenterally. (Please note recommendations accompanying vitamin K preparations prior to use.)

Fresh whole blood transfusions should be considered in cases of severe bleeding or prothrombinopenic states unresponsive to vitamin K_1.

Resumption of COUMADIN administration reverses the effect of vitamin K_1, and a therapeutic hypoprothrombinemia level can again be obtained.

SUPPLIED Tablets: COUMADIN (crystalline warfarin sodium, USP). For oral use, single scored, imprinted numerically with potency as follows: 2 mg lavender, 2½ mg orange, 5 mg peach, 7½ mg yellow, 10 mg white. In bottles of 100 and 1000. Also available in Hospital Unit-Dose blister package of 100.

Injection: Available as single injection units of amorphous warfarin sodium lyophilized for intravenous or intramuscular use in a box of 6 units for use immediately after reconstitution.

50 mg: Unit consists of 1 vial, 50 mg; sodium chloride, 10 mg; thimerosal, 0.2 mg. pH is adjusted with sodium hydroxide; accompanied by a 2 ml ampul Sterile Water for Injection.

Sterile Water for Injection contains no antimicrobial or other substance, and it is not suitable for intravascular injection without first having been made approximately isotonic by the addition of a suitable solute. Use only for reconstitution of the lyophilized product.

Injection manufactured by Lypho-Med, Inc., Chicago, Illinois 60651 for Endo Laboratories, Inc.

6037-16 Revised Jan. 1980

COUMADIN is an Endo registered U.S. trademark.

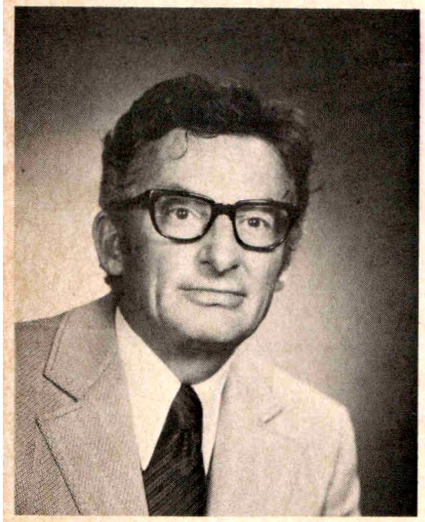
President's Page: Professional Societies and Industry



Robert O. Brandenburg, MD, FACC

The medical profession and medical industry have important reasons to complement each other. The goals of both are the same—to enhance the care of the patient who is ill and to prevent illness, when possible. This comment recognizes that if the industry's product is successful it will allow the company to flourish. While there are innumerable examples of advances in medical knowledge that have resulted from the support or cooperation of industry with the profession, this relationship has not reached an optimal level and some problems have developed at the interface of industry and our annual scientific meetings. Before I address this problem, I will make some observations on another area involving technology.

In the area of cardiovascular diseases, the technical developments in the last two decades have been particularly striking. These have resulted in major advances in our ability to recognize altered pathophysiology in patients with cardiovascular disease and better means of control of many cardiovascular problems. An unfortunate effect of these developments, yet to be resolved, is the expense and overlap of many of them. More important has been the decrease in clinical skills of many physicians as the tendency to become a technician instead of a clinician has grown. This unfortunate situation is furthered by federal and private funding agencies that underestimate and underreimburse the time, judgment and experience required to master the outpourings of our new machines. The problem tends to perpetuate itself, because our medical students observe and mimic, as well as note the economic advantage of being a "technician." This "negative" result of medical progress is a separate and important problem for the profession to resolve, and will not be further addressed here.

Rapid technologic development invariably leads to competition. This has been particularly true of the pacemaker industry with remarkably sophisticated units for multiple specific cardiac arrhythmia and conduction defects now available. Competition has led to increases in the number of companies, and a sharp increase in the activities of the marketing division of some of these companies. One consequence of this competition has been related to the replacement of hospitality suites (with a limited expenditure of space and money) at annual scientific meetings with large ballroom entertainment shows of the Las Vegas type with extensive arrays of food, beverages and name entertainers.

The expenditure of many thousands of dollars for these entertainments seems inappropriate at a professional scientific meeting. How much more relevant and beneficial would be the expenditure of such sums for the support of selective educational programs. It is recognized that a "marriage" of this type must give the supporting company appropriate exposure to its physician patrons while the professional society must retain the responsibility for establishing the ground rules for the expenditure and the maintenance of quality control.

It will be our responsibility to come forth with new, creative, innovative educational projects that will be attractive to industry, ones that will replace the lavish, expensive and inappropriate evenings seen at our annual meetings in recent years. Perpetuation of the current format will lead to ill feeling between industry and the profession, perpetuate a "bad image" and certainly will lead to restriction of this type of function at our meetings. The opportunity and need for change is apparent and will be of benefit to all concerned. I am pleased to report that in the past year we have had a meaningful dialog with several of the pacemaker companies. The results of these meetings, in most instances, will be reflected at our future annual scientific sessions.

Looking to the future, I believe that the opportunity and need for collaboration between the medical profession and industry has never been greater. As the funding for medical research becomes increasingly difficult it would appear appropriate, timely and to the advantage of both parties to explore and develop a relationship to enhance this endeavor.

Robert O. Brandenburg, MD, FACC
President
American College of Cardiology

CALENDAR OF EXTRAMURAL PROGRAMS

The aim of each program is to increase the theoretical and practical knowledge of the normal and abnormal function of the cardiovascular system in man. Most of the programs are pertinent to direct care of patients with heart disease. The need for such programs increases with the ever increasing amount of scientific and clinical data, the constant changes in technology and methodology, and the greater availability of therapeutic options. Today most cardiologists, internists and family practitioners feel the need of supplementing their professional reading by direct contact with the authors, research workers and leaders in the field.

To solve these problems the Committee selects each year series of carefully supervised programs which are usually preceded by extensive consultations with the program directors recruited among the foremost specialists educators and scientists in the field of clinical cardiology and allied basic science disciplines.

Although each program director is personally responsible for the choice of faculty, and the structure of the program, the Continuing Education Committee for Extramural Programs assumes the overall responsibility for the caliber of the postgraduate education and the relevance to the practice of cardiology. This is accomplished by the processes of meticulous scrutiny of the objectives, analysis of the educational methods, and studying the impact of each course on the knowledge and attitudes of the participants.

These programs should help each physician to keep up with the new knowledge, to put into practice the new advances and to retract gracefully from the obsolete and useless practices. An effective practitioner must learn and relearn, listen to new ideas, share past experiences and observe the work of his peers. The Continuing Education Committee for Extramural Programs of the American College of Cardiology believes that these goals can be accomplished by all members and nonmember professionals participating in our continuing education programs.

Leonard S. Dreifus, MD, FACC
Chairman, Continuing Education Committee for Extramural Programs

Programs and faculty are subject to change. For further information write Registration Secretary, Extramural Programs Department, American College of Cardiology, Heart House, 9111 Old Georgetown Road, Bethesda, Maryland 20014.

MARCH THROUGH AUGUST 1981

1981

To be arranged individually — **Preceptorships in Cardiology.** Arthur Selzer, FACC, director, Pacific Medical Center, San Francisco, CA

To be arranged individually — **Preceptorships in Cardiology.** Jules Constant, FACC, director. Buffalo General Hospital, Buffalo, NY

MAR. 30–APR. 3 — **Electrocardiographic Interpretation of Complex Arrhythmias: A Physiological Approach.** Charles Fisch, FACC and Douglas P. Zipes, FACC, directors. Krannert Institute of Cardiology, Indiana University Medical Center, Indianapolis, IN

APR. 6–15 — **Cardiology for the Consultant: A Clinician's Retreat.** E. Grey Dimond, FACC and James E. Crockett, FACC, directors. Rancho Santa Fe Inn, Rancho Santa Fe, CA

APR. 16–18 — **New Diagnostic and Therapeutic Modalities in Cardiology.** Edmund H. Sonnenblick, FACC and James Scheuer, FACC, directors. Grand Hyatt New York, New York, NY

APR. 23–24 — **Contemporary Phonocardiography (With Echocardiographic Correlation).** Morton E. Tavel, FACC, director. Methodist Hospital, Indianapolis, IN

APR. 27–MAY 1 — **Consultant's Course in Cardiology.** Richard Gorlin, FACC, Louis E. Teicholz, FACC, Simon Dack, FACC and Ephraim Donoso, FACC, directors. Mount Sinai Medical Center, New York, NY

APR. 29–MAY 1 — **Vectorcardiography—An Advanced Workshop.** Alberto Benchimol, FACC, director. Scottsdale Hilton Hotel, Scottsdale, AZ

MAY 7–9 — **The Pathology of Acquired Diseases of the Heart and Conduction System.** Jesse E. Edwards, FACC, Maurice Lev, FACC and Saroja Bharati, FACC, directors. Radisson Hotel, St. Paul, MN

MAY 7–9 — **Cardiac Emergencies.** Arthur Selzer, FACC and Richard Pasternak, co-directors. The Mark Hopkins, San Francisco, CA

MAY 7–9 — **Practical Cardiology for the Primary Care Physician,** Leonard S. Dreifus, FACC and Joel Morganroth, FACC, directors. Sarasota Hyatt Hotel, Sarasota, FL

MAY 13–15 — **Clinical Auscultation of the Heart.** W. Proctor Harvey, FACC, director and Antonio C. de Leon, Jr., FACC and John F. Stapleton, co-directors. Gorman Building Auditorium, Georgetown University Medical Center, Washington DC

MAY 14–16 — **Cardiac Diagnostic Techniques—A Clinical Perspective.** Arnold M. Weissler, FACC and Nicholas Z. Kerin, FACC, directors and Franklin E. Hull, FACC, S. C. Khullar, FACC and Melvin Rubenfire, FACC, co-directors. Detroit Plaza Hotel, Renaissance Center, Detroit, MI

MAY 18–22 — **Modern Cardiology.** J. Willis Hurst, FACC and Robert C. Schlant, FACC, directors. Sheraton Atlanta Hotel, Atlanta, GA

MAY 28–31 — **Sixth Annual Symposium on Cardiovascular Nursing.** Henry J. L. Marriott, FACC and Leo Schamroth, FACC, directors. Sheraton Sand Key Hotel, Clearwater Beach, FL

JUNE 17–19 — **The Patient with Arrhythmia—A Clinical Approach.** Ross D. Fletcher, FACC and W. Proctor Harvey, FACC, directors. Gorman Building Auditorium, Georgetown University Medical Center, Washington, DC

JUNE 30–JULY 3 — **Eighth Annual Symposium on Clinical Echocardiography: Current Applications and New Developments.** Arthur D. Hagan, FACC, director and Anthony N. DeMaria, FACC and William F. Friedman, FACC, co-directors. Snowbird Conference Center, Snowbird Ski and Summer Resort, Snowbird, UT

AUG. 29–31 — **Tutorials in the Tetons: Clinical Cardiology: Diagnostic and Therapeutic Advances (Seventh Annual).** Robert S. Eliot, FACC, director and James C. Buell, Timothy Fleming, FACC and Gerald L. Wolf, co-directors. Jackson Lake Lodge, Moran, WY

LEARNING CENTER: PROGRAM CALENDAR

The American College of Cardiology's Learning Center is located at the College's headquarters in Bethesda, Maryland. The purpose of the Learning Center is to support professional commitment to quality patient care by providing a standard of excellence in continuing medical education.

For additional information or a complete program calendar, contact the Program Registrar, Heart House Learning Center, American College of Cardiology, 9111 Old Georgetown Road, Bethesda, Maryland 20014. Telephone (301) 897-5400.

CARDIOLOGY BOARD REVIEW: Update in Cardiology

September 9–11, 1981 **Atlanta, Georgia**

Presented by: The American College of Cardiology

Directors: **J. WILLIS HURST, MD, FACC and ROBERT C. SCHLANT, MD, FACC**

For brochure and further information contact: Registration Secretary, Extramural Programs Department, American College of Cardiology, 9111 Old Georgetown Road, Bethesda, Maryland 20014. Telephone: Area Code 301 897-5400

ANNOUNCEMENT OF 1981 PEDIATRIC CARDIOLOGY EXAMINATION

The Sub-Board of Pediatric Cardiology of the American Board of Pediatrics will offer its next written examination on Friday, July 10, 1981.

The following criteria must be met to qualify to sit for the examination:

1. Certification by the American Board of Pediatrics;
2. Two years of full-time graduate training in an accredited pediatric cardiology program;
3. Letters of recommendation from individuals able to attest to the applicant's fellowship training.

Candidates who achieve a qualifying score on the written examination will be eligible for the oral examination. The oral portion of the examination will be held in October 1981, in New Orleans. A candidate must be successful on both the written and oral portions of the examination in order to be certified.

The registration period for the examination will extend from December 1, 1980 to March 31, 1981. Please contact the American Board of Pediatrics during that time if you wish to receive an application for the examination.

The application fee for the written portion of the examination is $300 ($150 processing, $50 registration, $100 examination fee). An additional fee of $150 will be payable upon receipt of an appointment for the oral examination.

Please direct inquiries to: American Board of Pediatrics
Suite 402, NCNB Plaza
136 East Rosemary Street
Chapel Hill, NC 27514
(919) 929-0461

NSTRUCTIONS FOR AUTHORS

The editors of THE AMERICAN JOURNAL OF CARDIOLOGY welcome concise articles devoted to cardiovascular disease. Articles must be contributed solely to THE AMERICAN JOURNAL OF CARDIOLOGY and become the property of the Publisher. The Publisher reserves copyright and renewal on all published material, and such material may not be reproduced in any form without the written permission of the Publisher. Statements in articles are the responsibility of the authors. Authors will assist the editors in the prompt processing of manuscripts if these instructions are followed:

HE WHOLE PAPER

Address manuscript to Managing Editor, nerican Journal of Cardiology, 666 Fifth e., New York, NY 10103.

Submit two copies of all elements of the ticle: text, references, legends, tables and jures.

Arrange the paper in this order: (1) title ge; (2) abstract; (3) text; (4) references; (5) gends; (6) tables; and (7) figures.

Number all pages in above sequence, beginning with title page as 1, abstract as 2, c.

Type all matter: (1) on 8½ × 11 opaque hite bond paper; (2) in duplicate; (3) on one de of each sheet only; (4) double-space; (5) ave wide margins, all four sides.

HE TITLE PAGE

Include first names, degrees and, where plicable, FACC for all authors.

Provide a short running title of 3 to 6 ords.

Insert at bottom: name and address of institution from which work originated plus information about grants.

Add at bottom the phrase "Address for reints: . . ." followed by full name and address th zip code.

HE ABSTRACT

Limit words as follows: 100 to 250 words for ajor articles; 50 to 100 words for case rts.

Add at end of abstract: list of 2 to 6 key ords and subjects for indexing.

HE TEXT

Type in duplicate; double-space.

Do not use abbreviations such as SVC, PW: write out superior vena cava, Wolff-rkinson-White.

Abbreviate measurements (mm, kcal and e like) as recommended in *Uniform Requirements for Manuscripts Submitted to omedical Journals,* published in *Am Rev spir Dis* 1979; 119:3–10; *Ann Intern Med* 79; 90:95–9; *Br Med J* 1979; 1:532–5; and *ncet* 1979:1:428–30.

- Cite in numerical order every reference, figure and table. (Order of mention in text determines the number given to each.)
- Place acknowledgments at end of text, before references.

THE REFERENCES

- Type in duplicate; double-space.
- Number the references in order in which they are mentioned in text.
- Provide concluding page numbers for all journal references and specific page numbers for all book references. Indicate all abstracts by the abbreviation (abstr).
- Follow the general arrangement, abbreviations and punctuation styles shown below.

THE FIGURE LEGENDS

- Start at top of new page.
- Type in duplicate; double-space.
- Identify at the end of each legend and in alphabetical order all abbreviations in the figure described.

THE TABLES

- Start each table at top of new page.
- Type in duplicate; double-space.
- Give each table a number (in roman numerals: Table I, II, etc) and a title. Number the tables in order in which they are mentioned in the text.
- Provide a footnote to each table—identifying in alphabetical order all abbreviations used.

THE FIGURES

- Submit 2 glossy prints (not originals) of each photo and drawing.
- Please note that art work of published articles will not be returned.
- Use black ink for all charts (line drawings) Make decimals, broken lines, etc. strong enough for reproduction.
- Use arrows to designate special features.
- Crop photomicrographs to show only essential field.
- Identify figures on back by number and author's name.
- Number figures in order in which they are mentioned in the text.
- Indicate top of each figure.
- Submit written permission from publisher and author to reproduce any previously published figures.
- Limit figures to number necessary for clarity. The publisher allows a limited sum toward reproduction.

Examples of Styles of References

For periodicals, follow INDEX MEDICUS, listing *all* authors (if there are 7 or more, list only 3 and add et al.):

31. Vismara LA, Vera Z, Miller RR, Mason DT. Efficacy of disopyramide phosphate in the treatment of refractory ventricular tachycardia. Am J Cardiol 1977; 39:1027–34.

(Author: please note that no periods are used after authors initials)

For chapter in book:

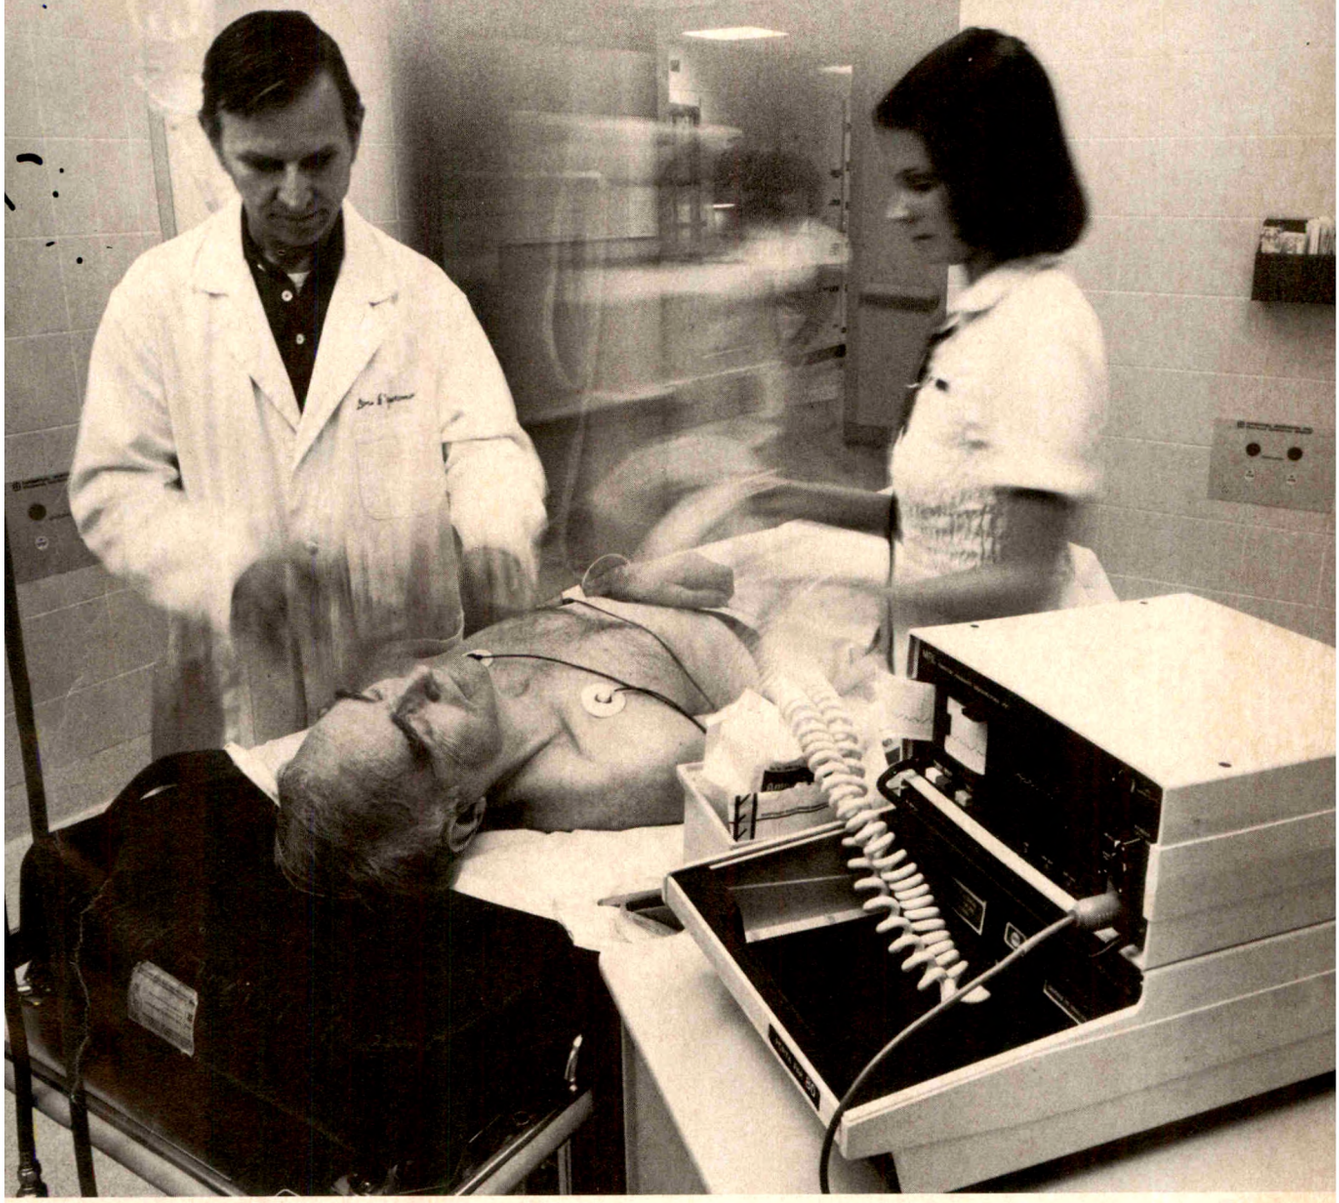
28. Schiebler GL, Van Mierop LHS, Krovetz LJ. Diseases of the tricuspid valve. In: Moss AJ, Adams F, eds. Heart Disease in Infants. Children and Adolescents. Baltimore: Williams & Wilkins, 1968:134–9.

For books (personal author or authors):

36. Berne E. Principles of Group Treatment. New York: Oxford University Press, 1966:26.

(Author: all book references should have specific page numbers.)

It's in Your Hands
The New Porta Pak80™



The Porta Pak 80 lets you stay with your patient. Everything you need to monitor, record and defibrillate is in your hands. It's easy to operate because stylus heat and ECG size adjustments are done for you, automatically. The large 5 inch monitor scope and easy to read chart recorder make evaluation of your patient's vital signs simpler, faster.

When you defibrillate, you can be sure that the energy you provide will be the energy you select, regardless of your patient. Our transthoracic load compensating module monitors your patient's resistance, adjusting the delivered energy. No other defibrillator does this.

Independent Power

The monitor/recorder can go with your patient. Just pull and lift off. It's that simple. The monitor and defibrillator may be operated from their own sealed battery back-up system, or from your power line. Power is available wherever you are.

At Medical Research Laborato we're making equipment simple, r reliable, and better, to help you vide your patients with the best possible.

Arrange to evaluate the Porta 80 now. Contact your local repres tative, or call 800/323-1415.

The New Porta Pak 80 fr MRL...it's like having another pair of hands.

A satisfied patient... because High Point's flavor makes reducing caffeine enjoyable.

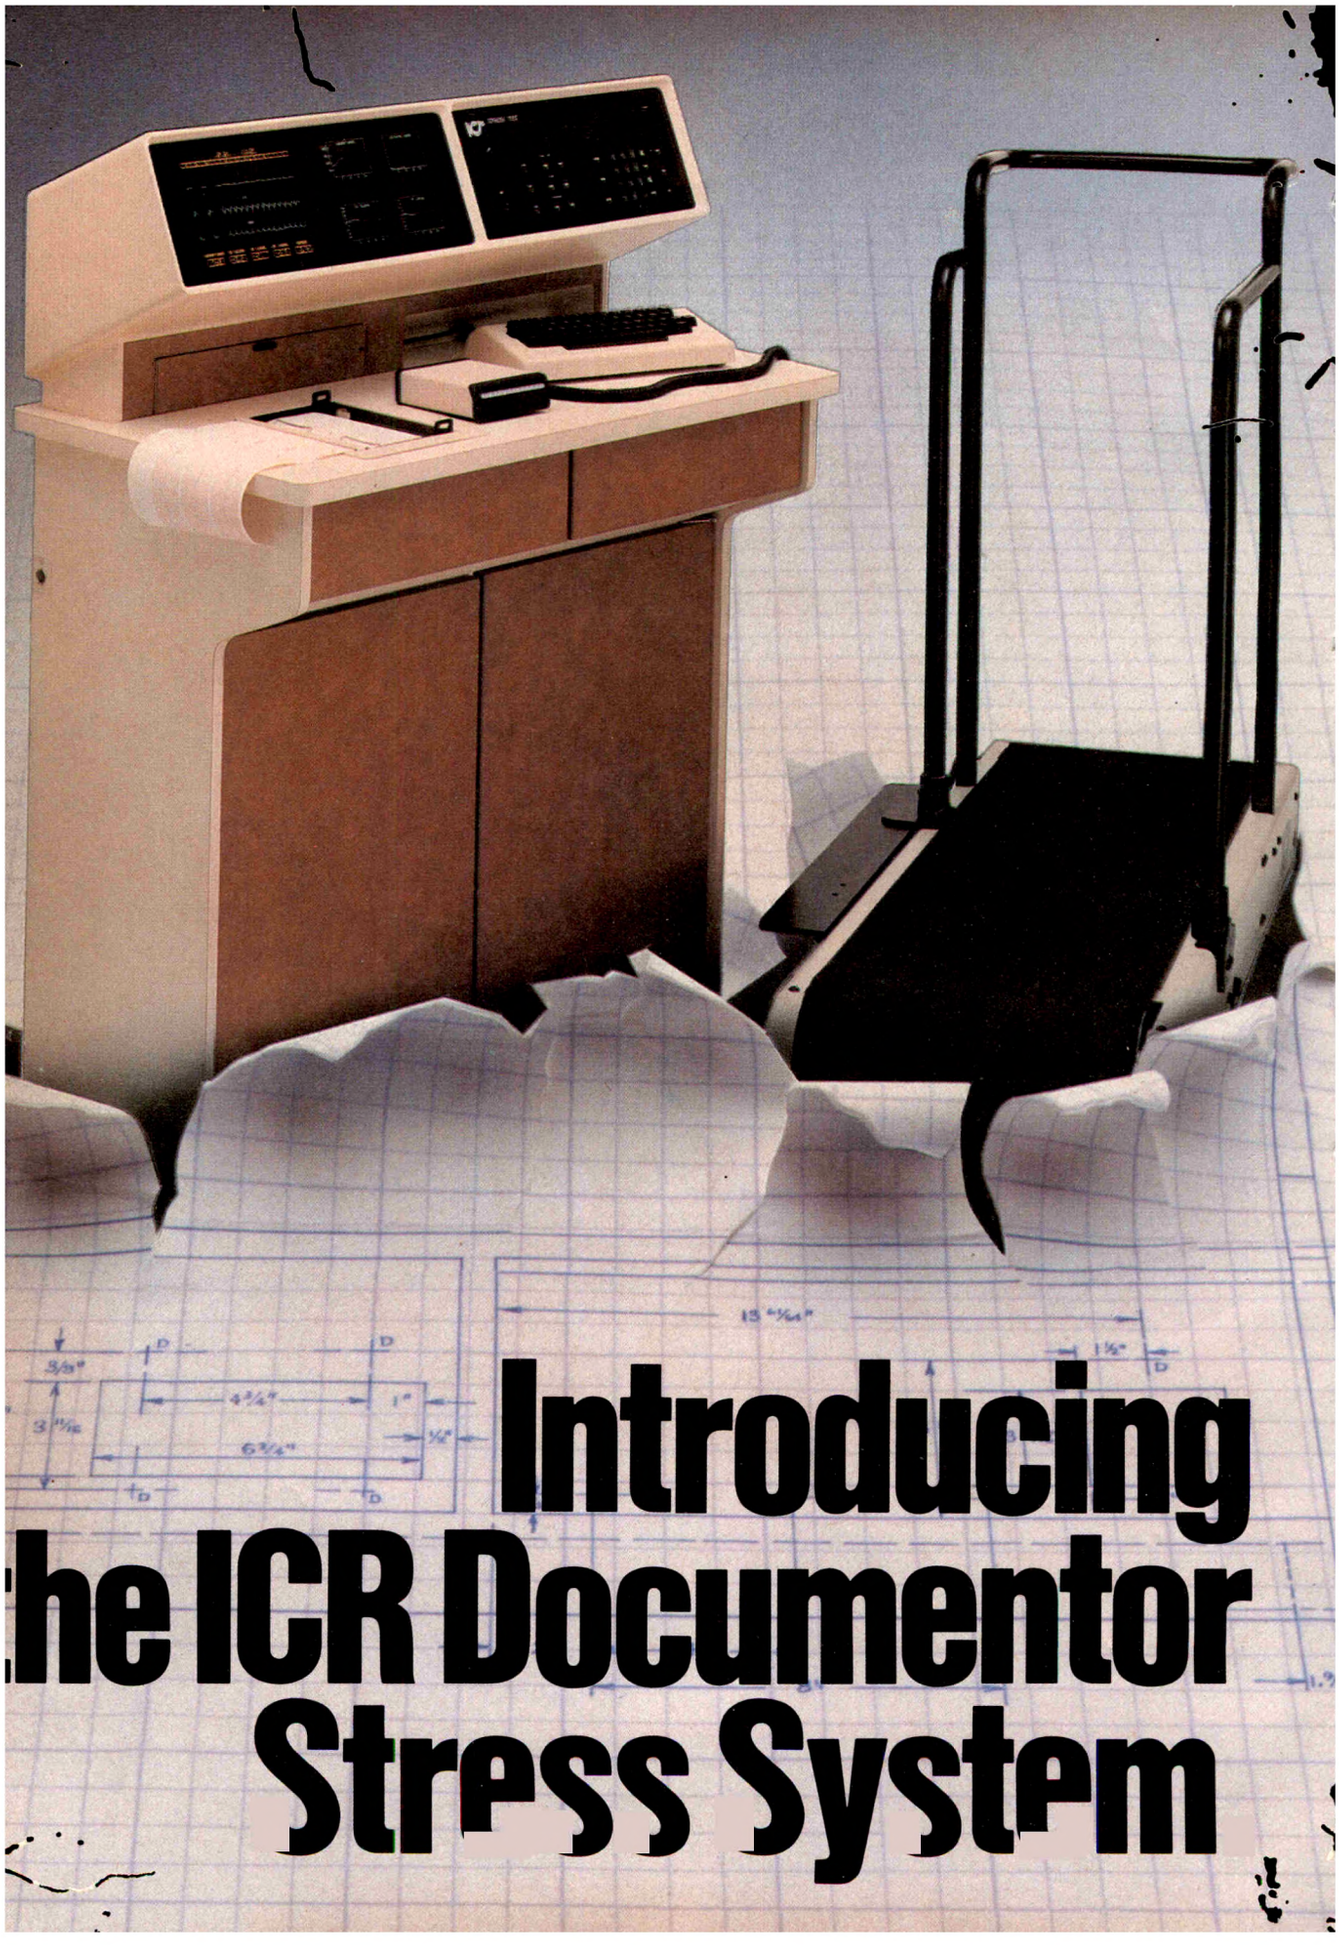
Recommending full-flavored High Point can improve patients' willingness to reduce caffeine intake.

When you feel that reduced caffeine consumption is therapeutically appropriate, consider recommending High Point ® Instant Decaffeinated Coffee. With High Point, your patients can enjoy the real coffee flavor they love with only 1-4 mg. of caffeine per 8-ounce cup, instead of the 45-125 mg. in a cup of regular instant coffee. High Point's great flavor helps patients comply with a caffeine-reduction regimen.

High Point's true coffee flavor starts with a unique blend of premium decaffeinated coffee beans. A patented extra step helps preserve th real coffee flavor ordinarily lost during conventional decaffeinated coffee processing — yet, High Point is 97% caffeine free.

High Point . . . when caffeine reductio is therapeutically appropriate.

For a coupon to obtain a free jar of High Point, send a request o your letterhead to: Professional Services Division, P.O. Box 171 Cincinnati, OH 45201.



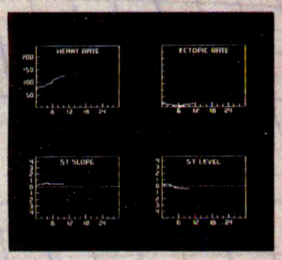
Introducing the ICR Documentor Stress System

See the new ICR Stress Systems at the A.C.C. Convention in San Francisco, March 16 to 19, Booth 1143.

4 Powerful advances in stress system capabilities from the leader in Holter technology.

Ten minutes of stress testing could be the key to your patient's life. Now, a breakthrough in stress technology from ICR enables you to find out more from those ten minutes than ever before possible.
Here's how.

1 More display data allows physician to make a better informed diagnosis.



With the ICR Documentor, you can get more perspectives on your patient's condition faster and more easily with a comprehensive selection of display data. One display presents up to four trends simultaneously. The other display shows (and freezes) your choice of one to twelve continuous ECG wave forms, plus numerical data and averaged wave configurations.

2 Meaningful report information in your selection of formats.

The ICR Documentor lets you select the information and report format most meaningful to your diagnosis. Its unique microprocessor design gives it enormous power in generating a wide variety of information, and unsurpassed flexibility of report formats.

3 Complete programming from pre-exercise to report.

The ICR Documentor is the first stress system to give you complete programming ability over every phase of the test, including: pre-test procedures, treadmill protocol, recovery procedures, and display and report information. The Documentor saves time and paperwork and allows you to concentrate on the more critical aspects of the test.

4 Three-button operation simplicity.

The Documentor can easily be programmed to store a wide variety of procedures to accommodate the requirements of different doctors. Once programmed, you can run any procedure simply by pushing three buttons.

The complete range of new ICR stress systems.

In addition to the Documentor, ICR is also introducing the Analyzer and Monitor. One of these systems is ideal for your practice, clinic or hospital. Each system can be upgraded quickly and easily in the field.

IREX

Systems that break the ultrasound barriers.

x is making breakthroughs in echocardi-
raphy. Technological breakthroughs.
eakthroughs that provide crisper images.
ore diagnostic capability. Greater flexi-
ity. And all at breakthrough prices.

x Phased Array Real Time Imaging System

amically focused 2-D sector scanner featuring unique 32 channel formance. Plus two sector-derived M-modes and a totally inde-dent M-mode. Compact, electronically steered, lightweight trans-ers. Optional heart sound/pulse and respiration module. Integral, anced design Sony® Beta format video cassette recorder. Simulta-us 2-D and M-mode black and white hard copy. And more.

x Cardio 80® Graphics Analyzer

ractive quantitative analysis of two-dimensional images, M-mode ocardiograms and other cardiodiagnostic data. 2-D analysis from play screen video or hard copy. Immediate printout of results. User grammable for analysis of research and special applications data. more.

Here's how Irex breaks the barriers

Technology. Innovative recording and display systems specifically designed for the cardiologist. Flexible, highly sensitive echo amplifier. Dynamically focused phased array. Ultrahigh resolution. Microprocessor control. State-of-the-art, phased array transducers. Software updating. High-speed digital scan conversion. All Irex designed. All Irex built. So you get leading-edge performance for improved diagnostic images.

Versatility. Broadest range of cardiac diagnostic capabilities in each Irex system. Highly flexible signal processing controls. So you can perform and analyze the study you want, the way you want to do it.

Mobility. Compact, durable systems that go where you need them, when you need them.

Commitment. The Irex commitment assures quality, reliability, continuing attention; prompt service from factory-trained Irex representatives; on-site training. So you get the most out of your Irex system.

Value. Irex systems give you features and sophistication that would cost you thousands more elsewhere.

Breakthrough technology at breakthrough price is what Irex echocardiography is all about. Return the coupon today for more ultra-exciting information.

Irex System II M-mode Echocardiograph
Today's leading M-mode echocardiographic system. The Irex time-tested and proven black and white recorder. Versatile user-oriented controls. High-sensitivity, noise-free echo amplification. Additional multichannel capability for diagnostic phonocardiograms, external pulse waves and auxiliary inputs. Expandable for future applications. All Irex innovations. And, yes, more.

ROYAL POSTGRADUATE MEDICAL SCHOOL

EUROPEAN CARDIOLOGY AT THE HAMMERSMITH

11–15 May 1981

ADVANCES AND NEW CONTROVERSIES 1981

This course will concentrate on important aspects of new advances and also upon new approaches to, and assessments of, old problems such as digitalis in sinus rhythm, the treatment of heart failure, pulmonary embolism, and anticoagulants in rheumatic heart disease. Pacemaking, electrophysiology, techniques of investigating myocardial ischaemia, echocardiography, calcium blocking agents, platelet agents and prostacyclins will be explored. Cardiac surgical topics, including circulatory assist devices, cardiac transplantation, long-term cardiopulmonary bypass, and valve replacement will also be considered.

A new feature will be introduced:—that of lunch-time sessions for small groups of participants who will discuss current problems in 'Meet the Experts' sessions and also have the opportunity to discuss the practical aspects of techniques of diagnosis and treatment in sessions on 'Practical Aspects of Investigation and Therapeutic Techniques'. In this way it is intended to increase the content of the course and also the contact between the participants and the lecturers.

Practical aspects: 'How to' sessions will include:

1 How to evaluate ambulatory ECG tapes
2 How to assess regional and overall left ventricular function of radioisotopes (gamma camera and nuclear stethoscope)
3 How to perform and analyse haemodynamic monitoring in the coronary care unit
4 How to perform diagnostic tests for coronary artery spasm
5 How to study arrhythmia by new electrophysiological approaches
6 How to evaluate total and regional myocardial perfusion and metabolism in man using computerised positron and single photon tomography in coronary artery disease and cardiomyopathy

'Meet the Experts' sessions will include:

1 New diagnostic approaches to the diagnosis of angina
2 New therapeutic approaches to angina
3 Acute myocardial infarction: a new approach in prospect
4 Classification and evaluation of cardiomyopathies
5 Recent advances in treatment of cardiomyopathies
6 Diagnosis and treatment of arrhythmias
7 Problems of pacemaking
8 Status of valve replacement today
9 Indications for surgery in coronary heart disease

Speakers include: J F Goodwin, A Maseri, H H Bentall, C M Oakley, D M Krikler, D Melrose, R N Sapsford and P Bourdillon (Royal Postgraduate Medical School) and experts from other international centres

Fee: (including catering) £75 for home students and member countries of the EEC £300 for overseas students

Application forms may be obtained from:

ıtermedics Pulse Generators

DICATIONS AND CONTRAINDICATIONS

The indications for cardiac pacing are increasing as pacemakers come more sophisticated and as advanced methods for patient nagement become more widespread. Generally accepted indications for long-term cardiac pacing include, but are not limited to: sick sinus syndrome; (2) chronic, symptomatic drug-resistant us arrhythmias, including sinus bradycardia, sinus arrest, and sinoatrial (S-A) block as seen in sick sinus syndrome; (3) chronic, symptomatic second-degree or third-degree A-V block; (4) recurrent Adams-Stokes syndrome; (5) bradycardia-tachycardia syndrome; (6) symptomatic bilateral bundle branch block; and (7) hypersensitive carotid sinus syndrome (carotid sinus syncope). In addition, certain patients presenting such symptoms as intractable, recurrent congestive heart failure; cerebral or renal insufficiency; or recurrent, drug-resistant tachyarrhythmias, and who have been shown to benefit from temporary cardiac pacing, are considered candidates for permanent cardiac pacing.

The indications for permanent pacing in the presence of acut myocardial infarction have not yet been rigorously defined. Fac to be considered include the location of the myocardial infarct, presence or absence of symptoms, ventricular rate, the mechan of the arrhythmias, and response to therapy. In general, sympto matic drug-resistant bradyarrhythmias which impair cardiac out are considered indications for pacing in patients with acute myo cardial infarction, regardless of infarct location.

A CyberLith® pacemaker put Cedric Turgeon back in the saddle.

TIMELY HEART SURGERY, AND A CYBERLITH® PACEMAKER, RESTORED THE YOUTHFUL VIGOR OF THIS YOUNG VICTIM OF A CONGENITAL CARDIAC DEFECT.

Jumping, running, playing, riding...all are normal, everyday pursuits of a typical pre-schooler. But Cedric Turgeon, at three, tired too easily, and ran out of breath too quickly. His symptoms became acute one day, and his parents rushed Cedric from his home in Tampa, Florida, to the hospital.

Doctors performed a cardiac catheterization to reveal the extent of the youngster's heart defects. Surgery was performed, at which time temporary cardiac pacing was required. Ten days later, a permanent pacemaker—a CyberLith—was implanted.

Now 4½ years old, Cedric is back to his old tricks, with one exception: his energetic momentum is unabated. His friends find Cedric as competitive as the best of them.

And Cedric needn't suffer a routine of frequent trips to the hospital, because Cedric's doctor monitors the pacemaker telephonically.

If changes are required, Cedric's physician can change pacing parameters noninvasively.

Cedric's CyberLith is just one model in the growing family of specialized Intermedics CyberLith pacemakers. These thin, lightweight units permit noninvasive programming of stimulation rate, pulse width, sensitivity level and pacing mode. And CyberLith's history of reliability is longer than any other multi-programmable pacemaker line.

CyberLith put Cedric back in the saddle. It could be the pacemaker of choice for your patients.

Location of some photos courtesy of The Dark Continent, Busch Gardens, Tampa, Florida.

There are no known contraindications to the use of pacemakers as a medical method for control of heart rate. However, body rejection phenomena such as local tissue reaction or skin necrosis, muscle and nerve stimulation, embolism, and cardiac tamponade have been reported.

CAUTION: Federal (U.S.A.) law restricts this device to sale by or on the order of a physician.

CARDIOQUIN®
TABLETS
(quinidine polygalacturonate)

- ☐ Greater GI tolerance than with quinidine sulfate
- ☐ Full quinidine cardiodynamics
- ☐ Convenient b.i.d. or t.i.d. dosage for most patients

CARDIOQUIN Tablets (quinidine polygalacturonate) are indicated in the treatment of a broad range of cardiac arrhythmias (see Brief Summary). After conversion to normal sinus rhythm—whether with CARDIOQUIN Tablets or electroconversion—only low b.i.d. or t.i.d. dosage of this unique polygalacturonate salt of quinidine is required for maintenance in most cases. The polygalacturonic acid serves as a buffering moiety. It protects the mucosa of the stomach and permits dependable absorption of the quinidine.*

*Aviado, D. M., Krantz and Carr's Pharmacologic Principles of Medical Practice, ed. 8, Baltimore, Williams and Wilkins Co., 1972, p. 456.

BRIEF SUMMARY—INDICATIONS: CARDIOQUIN Tablets (quinidine polygalacturonate) are indicated in the treatment of: premature atrial and ventricular contractions; paroxysmal atrial tachycardia; paroxysmal AV junctional rhythm; atrial flutter; paroxysmal atrial fibrillation; established atrial fibrillation when therapy is appropriate; paroxysmal ventricular tachycardia when not associated with complete heart-block; maintenance therapy after electrical conversion of atrial fibrillation and/or flutter. CONTRAINDICATIONS: Aberrant impulses and abnormal rhythms due to escape mechanisms should not be treated with quinidine. WARNING: In the treatment of atrial flutter reversion to sinus rhythm may be preceded by a progressive reduction in the degree of AV block to a 1:1 ratio and resulting extremely rapid ventricular rate. COMPOSITION: Each CARDIOQUIN Tablet (quinidine polygalacturonate 275 mg.) is equivalent in quinidine content to 3 grains quinidine sulfate. DOSAGE AND ADMINISTRATION: Dosage must be adjusted to individual needs, both for conversion and maintenance. An initial dose of 1 to 3 tablets may be used to terminate arrhythmias, and may be repeated in 3-4 hours. If normal sinus rhythm is not restored after 3 or 4 equal doses, the dose may be increased by ½ to 1 tablet (137.5 to 275 mg.) and administered three to four times before any further dosage increase. For maintenance, one tablet may be used two to three times a day; generally one tablet morning and night will be adequate. SUPPLIED: Uncoated, scored tablets in bottles of 100.
